The increased usage of hydrogen as a next generation clean fuel strongly demands the parallel development of room temperature and low power hydrogen sensors for their safety operation. In this work, we report strong evidence for preferential hydrogen adsorption at edge-sites in an edge oriented vertically aligned 3-D network of MoS2 flakes at room temperature. The vertically aligned edge-oriented MoS2 flakes were synthesised by a modified CVD process on a SiO2/Si substrate and confirmed by Scanning Electron Microscopy. Raman spectroscopy and PL spectroscopy reveal the signature of few-layer MoS2 flakes in the sample. The sensor’s performance was tested from room temperature to 150 °C for 1% hydrogen concentration. The device shows a fast response of 14.3 s even at room temperature. The sensitivity of the device strongly depends on temperature and increases from ~1% to ~11% as temperature increases. A detail hydrogen sensing mechanism was proposed based on the preferential hydrogen adsorption at MoS2 edge sites. The proposed gas sensing mechanism was verified by depositing ~2–3 nm of ZnO on top of the MoS2 flakes that partially passivated the edge sites. We found a decrease in the relative response of MoS2-ZnO hybrid structures. This study provides a strong experimental evidence for the role of MoS2 edge-sites in the fast hydrogen sensing and a step closer towards room temperature, low power (0.3 mW), hydrogen sensor development. Published by AIP Publishing. [http://dx.doi.org/10.1063/1.5000825]

Hydrogen is the efficient source of energy and produces zero pollution when burned with oxygen or air.1 Oxidation of hydrogen forms water as a side product, and an enormous amount of clean energy is generated. This energy is being widely used in space and civil transport. Nonetheless, hydrogen is explosive in nature when mixed with air even in a small concentration (~4%).2 Hence, fast detection of hydrogen gas well below the critical concentration is very crucial for the safety purpose of next generation clean energy production and regulation.

Recently, 2-D MoS2, a transition metal dichalcogenide (TMDC), has shown potential for various optical, electronic, and gas sensing applications due to their inborn direct band gap which allows better control over the carriers in contrast to other 2-D materials including graphene.3 Monolayer MoS2, ~0.65 nm thick, has the direct band gap of ~1.8 eV, while the band gap is decreased down to 1.2 eV and shifted to the indirect band gap as the number of layers increased.4 The semiconducting nature of MoS2 opens its applications in many areas such as optoelectronics,5 solar cells,6 water disinfection with visible light,7 nanoelectronic devices,8 and catalysis activities.9

Furthermore, atomically thin 2-D MoS2 showed its potential for gas sensing applications.10,11 Either MoS2 nanocomposites (MoS2-Pd) or MoS2 heterostructures (Pt–MoS2/MoO3) were utilized for hydrogen detection.12–14 In these reports, the sensitivity (ΔR/R) of a bare MoS2 sensor to hydrogen exposure was observed to be negligible, while high sensitivity and slow response for MoS2 nanocomposites and MoS2/Si heterostructures were observed. In most of these studies, basal plane MoS2 is used for gas sensing applications which is considered, thermodynamically, to be more inert than the edge sites in MoS2.15,16 Recently, researches focused on the growth of vertically aligned MoS217,18 with its edge sites perpendicular to the substrate plane and explored for hydrogen evolution reaction and for other enhanced catalytically activities.18,19 It was observed that the edge sites of MoS2 are much more reactive than the terrace of the basal plane MoS2.16 Hence, gas adsorption may greatly be augmented by the vertically aligned MoS2 films. However, there is no report in the literature especially on the highly reactive and exposed edges of MoS2 for hydrogen detection applications.12–14

In this paper, we present H2 gas sensing for an edge-oriented 3-D network of vertically aligned MoS2 flakes. The effect of different operating temperatures (28–150 °C) on the sensitivity, response time, and recovery time is studied with 1% concentration of hydrogen, which is well below the explosive limit of hydrogen in ambient. The overall response time in the range of 14.3 s to 20.4 s is observed. To confirm the role of MoS2 edges for hydrogen sensing, a thin ZnO film (2–3 nm) was deposited on MoS2 flakes, and the sensor response was studied for MoS2-ZnO hybrid structures. It is found that the sensor response decreased nearly 50% due to partial passivation of favorable sites for hydrogen adsorption in MoS2 flakes. This study clearly revealed the role of edge sites for preferential hydrogen adsorption and its fast detection.
MoS$_2$ edge-oriented vertically aligned flakes were synthesized on a Si/SiO$_2$ substrate via a modified tube-in-tube CVD process. For more details, see the supplementary material. In brief, high purity MoO$_3$ (99.97%, Sigma Aldrich) and sulfur powder (99.98%, Sigma Aldrich) were used for the growth of MoS$_2$ flakes. The cleaned substrate was placed on the top of MoO$_3$ powder boat. The small tube with one end closed loaded with powders, and the substrate was placed inside a bigger quartz tube in such a way that the close end faced the gas inlet (see Fig. S1 in the supplementary material). Ar gas flow was maintained at 225 sccm throughout the deposition. The close end of the small tube was in zone 1 (MoO$_3$), and the open end was in zone 2 (S). The growth temperature for zone 1 and zone 2 was fixed at 800°C and 350°C, respectively (see Fig. S1 in the supplementary material). The growth time was 30 min followed by cooling to RT at the same Ar flow.

The surface morphology of as-grown MoS$_2$ flakes was studied using a FEI Helios Nano Lab 400 with a probe current of 0.34 nA and an accelerating voltage of 10 kV. Raman and photoluminescence (PL) were done using a HORIBA HR320 spectrometer. A 532 nm laser was used as the excitation source with a power of 500 μW to avoid any heating effect on the samples. Metal contacts in the shape of circular dots of Au/Cr having a thickness 250/3–5 nm with 100 μm diameter were deposited through physical mask by thermal evaporation. The separation between the two metal dots was ~100 μm. The gas sensor response was measured with 1% hydrogen concentration diluted with 99% argon in a home-built gas sensing system equipped with a mass flow controller and a proportional–integral–derivative (PID) controlled heater for accurate measurements. The sensing measurement was done in the operating temperature range of 28–150°C using a computer controlled Keithley 4200.

Figure 1(a) shows the field emission-scanning electron microscopy (FE-SEM) images of as-grown MoS$_2$ flakes. The results clearly indicate that these flakes are vertically grown from the substrate and interconnected to each other and form an interconnecting 3-D network. The dotted line in Fig. 1(a) is the guide to the eye for MoS$_2$ interconnection from one end to another end. The inset shows the high magnified FE-SEM image of flakes. The thickness of typical MoS$_2$ flakes, as shown in the high magnified FE-SEM image, is ~1.5 nm, which confirms that MoS$_2$ flakes are few-layered in nature. The Raman spectrum of edge-oriented MoS$_2$ flakes is shown in Fig. 1(b). Three coincide Raman modes of the Raman signal from three different areas are observed and showed the uniformity of the few-layer MoS$_2$ films. Two Raman modes are active at Raman absorbed wavenumbers of 384.90 cm$^{-1}$ and 410.05 cm$^{-1}$ which are attributed to $E_{2g}^1$ (in-plane mode) and $A_{1g}$ (out-of-plane mode) modes of MoS$_2$, respectively, as shown in Fig. 1(b).$^{20}$

The wave number difference between the $E_{2g}^1$ and $A_{1g}$ modes is 25.15 cm$^{-1}$, which shows that MoS$_2$ has a few-layered structure which is also confirmed by FE-SEM analysis.$^{20}$ The PL spectra of these edge-oriented MoS$_2$ flakes were also recorded and are shown in the supplementary material (Fig. S2). Two peaks corresponding to A and B excitons are observed in the energy range of 1.82 eV–1.95 eV. This is in good agreement with the previous report for the few-layered MoS$_2$ structure.$^{21}$

Finally, the edge-oriented MoS$_2$ flakes were tested for 1% hydrogen detection at different temperatures. The gas adsorption behavior of MoS$_2$ flakes is determined by the variation in the resistance at different operating temperatures (28–150°C). We measured the resistance of the film by two-probe method with the Au/Cr contacts made on top of the MoS$_2$ flakes. Figure 1(c) shows the 3-D schematic of the hydrogen gas sensing device, and Fig. 1(d) shows the T–V characteristics of the device at 125°C with and without hydrogen gas exposure. The exposed area between the two contacts was responsible for the gas sensing behavior of interconnected MoS$_2$ flakes. I–V characteristics clearly show that with the hydrogen exposure, the current is decreased and linear in nature. MoS$_2$ flakes are n-type in nature, and a decrease in the current implies that the hydrogen gas sensing takes the electron from the n-type MoS$_2$ flakes. So, as the hydrogen gas is exposed to the MoS$_2$ flakes, it increases the resistance between the two contacts by taking the electrons from the film, and thus, there is a decrease in the current. I–V characteristics of the MoS$_2$ sensor are linear in nature for all temperatures with and without hydrogen exposure. Linear characteristics of the I–V curve also reliable from the matching work function of metal contact (5.1 eV) and MoS$_2$ flakes (4.2–5.2 eV).$^{22,23}$ In our case, I–V characteristics of the MoS$_2$ sensor is linear in nature for all temperatures with and without hydrogen exposure, and we observed the lowest power consumption of 0.3 mW in comparison to the literature.$^{24,25}$

Figure 2(a) shows the change in sensitivity ((R$_{\text{Hydrogen}}$/R$_{\text{Air}}$) of the MoS$_2$ sensor with temperature. The figure clearly shows that the resistance and hence the sensitivity of the sensor increase with hydrogen exposure. As the sensing
temperature increases from room temperature to 150 °C, the sensitivity increases from ∼1% to ∼11%. The response and recovery time of the edge-oriented MoS2 vertically aligned flakes are also plotted in Figs. 2(b) and 2(c), respectively. In the temperature range of 28–150 °C, the response time has changed from 14.3 s to 20.4 s. The observed overall response time is much lower than that for the other reported MoS2 based hydrogen sensors. In a high operating temperature range (100–150 °C), the response time reaches a nearly saturated value around 18 s. The recovery time of the sensor is in the range of 108.3 s to 160.4 s. In a high-temperature range (100–150 °C), the device recovery time varies from 108 s to 129 s, which shows that the desorption rate of hydrogen at high temperature is nearly constant. Figure 2(d) shows the variation of sensitivity with temperature. It shows that sensitivity increases linearly up to 11% with temperature. The cyclability and stability of the sensor are tested for nearly 40 cycles and revealed almost the same sensitivity with a little change of ±5% for all the temperatures, which clearly signifies that the passivation of edge defects with hydrogen exposure is reversible in nature.

Table I summarizes the characteristics of the hydrogen sensor based on the MoS2 flakes, MoS2 composites and other nanostructures reported in the literature along with sensor characteristics in the present work. In all these reports, the hydrogen sensor made of edge-oriented MoS2 flakes from this work shows the least or comparable response time for the fast detection of hydrogen at RT.

To understand the gas sensing behaviors for edge expose MoS2 flakes, we consider the preferable interaction of hydrogen molecules with MoS2 flakes. It is reported that thermodynamics favor to grow a basal plane as inert in comparison to the edge sites in MoS2 flakes. The more defective nature of as grown edges in MoS2 flakes is being utilized to enhance their catalytic activities. Here, it is observed that MoS2 flakes are highly conducting in nature at all operating temperatures. This behavior can be attributed to the formation of favorable S vacancy at the edges which may be created during the synthesis of MoS2 flakes. It is important to note that the energy required to remove the S atom and Mo atom from the MoS2 layer is reported to be 6.1 eV and 13.9 eV, respectively. So, the formation of S vacancies is more favorable during the growth. The S vacancy at the edges makes MoS2 flakes as Mo-rich and responsible for their metallic like behavior. In the 3-D interconnected network of MoS2 layer, nanowires, edges of MoS2 behave as one-dimensional metallic structures due to the presence of localized metallic states, which is schematically shown as yellow lines in Fig. 3(a).

Position dependent adsorption of hydrogen molecules on MoS2 was studied by the first principle calculations. Hydrogen molecule adsorption is determined by the negative adsorption energy, and hence, the most stable adsorption configuration on MoS2 flakes for hydrogen gas is theoretically calculated. The adsorption energy is determined by $E_a = E_{\text{MoS}_2 + \text{molecule}} - (E_{\text{MoS}_2} + E_{\text{molecule}})$, where $E_{\text{MoS}_2 + \text{molecule}}$ is the net energy of MoS2 and the adsorbed gas molecule and $E_{\text{MoS}_2}$ and $E_{\text{molecule}}$ are the total energy of MoS2 and the single gas molecule. Negative adsorption energy means that the process is exothermic, and gas molecules have a strong interaction with MoS2. Among the four available adsorption sites in MoS2 [top of hexagon (H), top of Mo atoms (TM), top of S atoms (TS), and top of Mo-S bonds (B)], as shown in Fig. 3(b), the TM sites have the adsorption energy of −82 meV, H sites have the adsorption energy of −70 meV, while TS sites have the adsorption energy of −49 meV. A similar trend in adsorption energy for hydrogen molecules at different sites in MoS2 with a higher value for the TM site (−131.61 meV) was also observed in another report. Therefore, the hydrogen molecule has the highest probability to adsorb at Mo atom sites. It may be a non-zero probability for hydrogen gas adsorption at inert basal planes. However, in our case, the probability of interacting hydrogen at edges is much higher than the basal plane because of their defective nature. The calculated charge transfer from MoS2 to the hydrogen molecule to be 0.05 e−.

and 0.004e,\(^{32}\) respectively, which implies that hydrogen plays as an electron acceptor.

From the above details, it is clear that hydrogen adsorption is most favorable along the edges of MoS\(_2\) flakes rather than the basal plane and hydrogen behaves as the electron acceptor in nature for intrinsic n-type MoS\(_2\).\(^{33,34}\) The edges of MoS\(_2\) behave like metallic inter-connecting wires,\(^{15}\) and at room temperature, hydrogen is easily adsorbed. This increases the charge transfer of the MoS\(_2\) flakes with exposed hydrogen gas at a much faster rate than the basal plane MoS\(_2\). Thus, at room temperature, the device shows a very fast response time.

To understand the temperature dependent increase in sensitivity, we closely observed I-V characteristics and the resistance of the sensing device, with temperature in the absence of hydrogen. As the sensing temperature increases from 28 to 50 °C, the base resistance decreases dramatically as shown in Fig. 3(c). At room temperature, the device shows the higher base resistance of around 2.48 Ω, and then, it decreases to a minimum value of 2.05 Ω as the temperature increases from 28 °C to 50 °C. After 50 °C, the base resistance increases linearly with an increase in the temperature. This sharp decrease in the base resistance can be understood on the basis of the oxygen desorption from S vacancy sites in MoS\(_2\) edges.

The oxygen adsorption plays a crucial role in inducing the doping effect in MoS\(_2\) due to charge transfer.\(^{35}\) The role of oxygen on MoS\(_2\) and at the S vacancy sites was studied previously.\(^{36}\) The first principles calculations were performed to calculate the binding energy of the oxygen molecule at defect free MoS\(_2\) planes and at S vacancy sites in MoS\(_2\) and the charge transfer to the adsorbed oxygen at these sites. The calculated binding energies between MoS\(_2\) and S vacancy sites for adsorbed oxygen were found to be 0.102 eV and 2.395 eV, which clearly indicate the physical adsorption and chemically adsorption nature of oxygen at two different sites, respectively. The calculated charge transfer between physically adsorbed oxygen to MoS\(_2\) was 0.021e, while chemically adsorbed oxygen at the S vacancies was higher, which is 0.997e.

Thus, adsorbed oxygen bound at the S vacancies takes much more electrons than from MoS\(_2\) flakes. Hence, at room temperature, adsorbed oxygen increased the resistance of the edge oriented MoS\(_2\) flakes. Therefore, the base resistance in the absence of hydrogen gas at room temperature is higher than the other operating temperature as shown in Fig. 3(c). However, as the temperature increased from room temperature to 50°C, the vacuum and heating simultaneously helped to remove the ambient oxygen from the flakes.\(^{37}\) This leads to a fast decrease in the base resistance of the sensor with different temperatures and reaches a nearly intrinsic value as compared to room temperature even in the absence of hydrogen gas. With a further increase in the temperature, from 50°C to 150°C, the base resistance increases linearly, which may be due to the scattering of carriers in metallic like edges in MoS\(_2\) flakes. The desorption of the O\(_2\) molecule creates fresh active and favorable S vacancy sites for the adsorption of H\(_2\) molecules. Hence, the film shows linearly increased sensitivity with temperature, and this phenomenon is continued as we further increased the temperature up to 150°C.

To validate the proposed hypothesis and further understand the role of availability of favorable sites for hydrogen sensing, we deposited the 2–3 nm thin ZnO film using the RF magnetron sputtering technique on MoS\(_2\) flakes and formed a hybrid structure of MoS\(_2\)-ZnO. The deposited ZnO film is not very thick to completely cover the MoS\(_2\) flakes. It can partially passivate the edges of the MoS\(_2\) flakes. Since MoS\(_2\) flakes are vertically aligned, the probability to deposit ZnO on the edges is high. Thus, the number of favorable sites for the hydrogen adsorption may be reduced. The sensor response of MoS\(_2\)-ZnO hybrid structures was measured from room temperature to 150°C for 1% hydrogen under identical
conditions. The sensitivity of the MoS2-ZnO hybrid is shown in Fig. 3(d). The results revealed that sensitivity is nearly the same at room temperature, while it is reduced at a higher temperature. The decrease in the sensitivity of MoS2-ZnO hybrid structures is the clear indication of the partial passivation of MoS2 edge defect sites and decrease in sensitivity up to 50%, shown in Fig. 3(d). This provides strong experimental evidence of MoS2 edge sites for hydrogen gas sensing applications.

In conclusion, we fabricated a 3-D network of edge-oriented vertically aligned MoS2 flakes on a SiO2/Si substrate via a modified tube-in-tube chemical vapor technique. Raman, PL, and FE-SEM results confirm that the synthesized flakes are edge oriented vertically aligned and few layered in nature. The response of this MoS2 interconnected network was tested for 1% hydrogen in the operating temperature range of 28–150 °C. The device shows a fast response time of 14.3 s even at room temperature. The higher sensitivity of 1% to 11% from 28 to 150 °C was attributed to the presence of the favorable adsorption sites at the edges of MoS2 flakes. The role of edge sites in hydrogen adsorption is confirmed by partially passivating the edges by depositing the 2–3 nm ZnO film on MoS2 flakes. This study offers MoS2 vertically aligned flakes as a promising candidate for the development of fast and low power hydrogen sensors.
