ACKNOWLEDGEMENTS

I thank Dr. Timothy Bonner for serving as my advisor, his instruction in and out of the classroom, countless discussions of fishes, inspiring my success, and sharing a definitive love for Texas. I thank Dr. Clay Green for serving on my committee, increasing my appreciation of ecology and conservation, and constantly reminding me there is more out there than fish. I thank Dr. Gary Garrett for serving on my committee, his extensive service and dedication to Texas fishes, and passing along words of wisdom from Clark Hubbs. I thank Dr. Thom Hardy for his never ending patience with non-engineers, sharing his strong work ethic, and continually pushing the envelope of my critical thinking skills. I also thank the great ones that laid the foundation for the work I've grown to love so much: David Starr Jordan, Charles Gilbert, Charles Girard, Edward Cope, Barton Evermann, Carl Hubbs, Clark Hubbs, Royal Suttkus, and the inventor of the common sense seine.

I thank numerous colleagues for greatly contributing to fieldwork, providing thought provoking discussion, and endless encouragement. I thank The A-Team: Chad Thomas, Casey Williams, Dusty McDonald, Brad Littrell, Tom Heard, and Jackie Watson for setting a high standard. I thank Zachary Shattuck for his continued encouragement, devoted friendship, endless enthusiasm, and magnificent passion for the field of fish ecology. I thank Kristy Kollaus for her companionship in and out of the classroom, her continued understanding of my near-obsession with fish, and her exemplary patience. I thank Robby Maxwell, Danielle Livingston, Clara Folb,

Sara McMillan, Nathan Dammeyer, Benjamin Labay, and numerous ichthyology students for help in the field and providing a bright future for the study of fish ecology at Texas State University-San Marcos.

This thesis would never have been possible were it not for my family. I thank my father Jack Richard Perkin for providing a kindhearted role model, countless sacrifices, and instilling in me his passion for professional excellence and the great outdoors. I thank my great uncle Rick Perkin for providing life-long memories of outdoor adventures and cultivating my appreciation for the natural world. I thank my grandfather Jack Perkin for his service to this country, his incarnation of John Wayne, and providing example of what it is to be a man. A special thanks to my grandmother Melba Ellinger and dear friend Lynn Lee for their never-ending support and devotion to my education.

This manuscript was submitted on May 26, 2009.

CHAPTER I

HISTORICAL COMPOSITION AND LONG-TERM TRENDS OF FISH ASSEMBLAGES IN TWO TEXAS RIVERS

INTRODUCTION

A suite of biotic and abiotic structuring mechanisms influence the natural occurrence and abundance of warm-water stream fishes through time and space (Matthews 1998). However, anthropogenic alterations of riverine environments disrupt structuring mechanisms, causing minor and major changes to stream fish assemblages (Winston et al. 1991; Aadland 1993; Davis 1997; Keenlyne 1997; Luttrell et al. 1999; Haro et al. 2000; Garrett et al. 2002; Edwards et al. 2004; Rinne et al. 2005b; Adams et al. 2006; Poff et al. 2007; Runyan 2007). Major changes to stream fish assemblages include the extinction or imperilment of endemic freshwater fishes. Percent of extinct or imperiled native freshwater fishes is 21% in North America (Leidy and Moyle 1998), 28% in southeastern USA (Warren et al. 2000), and 48% in southwestern USA (Warren and Burr 1994). In Texas, 44% of native freshwater fishes are considered imperiled (Hubbs et al. 2008). Despite the alarming rate of species imperilment and the subsequent increasing trend of fish homogenization (Rahel 2000), successful protection of warm-water stream fishes can be enhanced with water quality and quantity management (Angermeier 1995; Pister 1999; Richter et al. 2003; Petts et al. 2006).

Water quantity management in Southwestern United States streams is necessary due to increasing aridity (Martin and Menringer 1965) and demand for water (McCarl et al. 1999). Low-head dams and deep storage reservoirs are common practices for securing adequate year-round water supply and hydroelectric power for urbanized or industrialized areas (Baxter 1977). Detrimental effects of reservoirs on aquatic biota are well documented (Richter et al. 1997); among others, a notable effect of reservoir construction is alteration of natural flow regime (Poff et al. 1997). Reservoirs can cause drastic reduction or elimination of small and large floods (Runyan 2007) and therefore alter numerous biotic (e.g., spawning cues; Bonner and Wilde 2000) and abiotic (e.g., stream morphology; Poff et al. 1997) factors for considerable distances downstream (Edwards 1978). Furthermore, detrimental effects continue upstream of impoundments by inundation of habitat, conversion of lotic to lentic water (Edwards 1978) and disruption of migration patterns (Bonner and Wilde 2000).

A growing body of literature exists for historical changes in stream fish assemblages in relation to anthropogenic stream alteration (see Rinne et al. 2005a). However, additional research is necessary since streams are among the most negatively impacted environments by human activity (Helfman 2007) and stream fish assemblage changes have been poorly documented with regard to the degree of existing alteration (Quinn and Kwak 2003). Analysis of long-term trends in stream-dwelling fish assemblages provides several benefits including better understanding of the extent and magnitude of anthropogenic alteration (Calamusso et al. 2005), identifying species decline prior to imperilment (Runyan 2007), consideration of changes over broad time scales (e.g., > 60 years; Gido et al. 2002) and quantifying species loss due to extirpation

or extinction (Mercado-Silva et al. 2006). Quantifying stream fish assemblage changes following stream alteration is limited by availability of baseline data collected prior to alteration (Gido et al. 2002), a limitation that has enhanced the value of historical museum collections (Suarez and Tsutsui 2004).

Purpose of this study was to assess the effects of a deep storage, hydroelectric reservoir as well as tributary impoundments and watershed flood retarding and retention dams on fish assemblages of the Guadalupe River basin, Texas. More specifically, I sought to assess changes in mean annual flow, frequency of flood events, fish assemblage structure, abundance of specific taxa, and reproductive and trophic guild abundances following anthropogenic alteration of flow regimes within a semi-arid watershed.

STUDY AREA

The Guadalupe River originates at the confluence of the North Fork Guadalupe River and South Fork Guadalupe River near the City of Hunt, Kerr County, Texas (Figure 1). The total drainage area is 15,700 km² as it flows about 370 km southeast toward the Gulf of Mexico. Among the seven mainstem impoundments on the Guadalupe River, Canyon Lake Reservoir was constructed in 1964. With a maximum depth of about 40 m and with a surface area of 3,300 ha, Canyon Lake Reservoir is the only deep storage reservoir within the Guadalupe River basin, representing the most significant alteration of mainstem discharge (Young et al. 1972; Edwards 1978). Remaining mainstem reservoirs are impounded by low-head dams (maximum height: 12 m), constructing from 1928 through 1931 in the lower Guadalupe River (Young et al. 1972).

The San Marcos River, among the largest tributaries of the Guadalupe River, originates from artesian springs in the City of San Marcos, Hays County, Texas and flows about 120 km before reaching its confluence with the Guadalupe River near Gonzales, Gonzales County, Texas. San Marcos River has seven low-head dams (maximum height: 6 m) and numerous low water crossings constructed between 1849 and 1901 (Taylor 1904). Several low-head dams were constructed in the upper Blanco River, a tributary of the San Marcos River, by Civilian Conservation Corps in mid 1930s and by private landowners through the 1950s (pers. comm. H. Hammond, Blanco County landowner). Flood retarding structures were constructed by the Natural Resource Conservation Service (NRCS) in the Plum Creek and York Creek drainages of the lower San Marcos River in the mid 1960s and 1970s (pers. comm. I. Morales, District Conservationist, NRCS, Lockhart, Texas). Flood retention structures were constructed by NRCS in the upper San Marcos River watershed in the 1980s (Woods and Earl 2002).

METHODS

Daily discharges were obtained from three locations on the Guadalupe River (US Geological Survey Station 08168500, New Braunfels, Texas; USGS Station 08176500, Victoria, Texas; USGS Station 08167500, Spring Branch, Texas) and one location on the San Marcos River (USGS Station 08172000, Luling, Texas; Figure 1). These locations encompass the largest available spatiotemporal range in drainage discharge (350 km mainstem Guadalupe River; 1927 - 2007 for Station 08168500; 1934 - 2007 for Station 08176500; 1922 - 2007 for Station 08167500, and 1938 - 2007 for Station 08172000). For each Guadalupe mainstem site, discharge data were divided into Period I (earliest

record – 1963) and Period II (1965 – 2007), using the completion of Canyon Reservoir (1964) as the environmental impact. For the San Marcos River, a break in ichthyological data ranging 1963 to 1976 was used to define Period I (1927-1963) and Period II (1976-2006), which generally corresponds with pre- and post construction of water retarding and retention dams developed in the upper and lower watershed from late 1950s through early 1980s. Changes in frequency of small and large floods and mean annual discharge between periods were assessed with Indicators of Hydrologic Alteration, v. 7.0.3 (IHA). Flood frequency and mean annual discharge were used because of strong interrelationship among these parameters, fish habitat availability, and stream morphology (Richter et al. 1996; Runyan 2007). Small floods were defined as high flow events (i.e., exceeding 75% of discharge in Period I) with recurrences of at least 2 years. Large floods were defined as high flow events with recurrences of at least 10 years.

Historical ichthyo faunal collections from the Guadalupe River and San Marcos River drainages were obtained from museum collections, agency reports, unpublished records, and published documents. Museum collections were obtained from the Texas Natural History Museum (TNHC; University of Texas), Texas Cooperative Wildlife Collection (TCWC; Texas A&M University), Tulane Museum of Natural History (Tulane), University of Kansas Natural History Museum (KU), University of Michigan Museum of Zoology (UMMZ), Field Museum of Natural History (FMNH; Chicago, Illinois), San Noble Oklahoma Museum of Natural History (OMNH; University of Oklahoma), and the National Museum of Natural History (NMNH; Smithsonian). Agency reports and published data included Texas Game and Fish Commission (TGFC, now Texas Parks and Wildlife, 1956), TGFC (1958), TGFC (1962), TGCF (1973), U.S.

Fish and Wildlife Service (1976), Underwood and Dronen (1984), Longley et al. (1996), Terre and Magnilia (1996), Kelsey (1997) and Longley et al. (1998). Unpublished data were obtained from K. Mayes (Texas Parks and Wildlife Department), B. Beard (Texas Parks and Wildlife Department), B. Moring (US Geological Survey) and B. Whiteside, T. Bonner and P. Bean (Texas State University-San Marcos). Species occurrences and abundances, date and location of collection, principal collector, and methods of collection were obtained from all collections (Appendix I, II, and III).

Historical ichthyofaunal collections were filtered before assessing assemblage occurrence and abundance analyses (Runyan 2007). Species list was compared to expected ichthyofaunal list for the Guadalupe River drainage (Conner and Suttkus 1986; Thomas et al. 2007; Hubbs et al. 2008). Questionable identifications were confirmed or refuted with voucher specimens. Others were noted and removed when voucher specimens were not taken or available. Tributaries lacking sufficient temporal collections to infer assemblage changes were removed from abundance analyses. Consequently, abundance analyses were performed with assemblage data only from mainstem Guadalupe River and San Marcos River. Upper and lower Guadalupe River sections were analyzed independently because of the potential for longitudinal differences in fish assemblages. Seining and electrofishing collections within each river were retained if the collection had >5% of the total taxa found in the drainage and if the collection had >0.1% of the total number of individuals collected to improve the likelihood of the collection being a representative sample of the fish assemblage on a given date.

Fish relative abundance was calculated for each collection retained for analyses. Among collections, relative abundances of a species were $\log_{10}(N+1)$ -transformed and

plotted through time. Time represented the number of days from the first collection (June 23, 1938). Simple linear regression was used to test if slope of relative abundance differed ($\alpha = 0.05$) through time. Populations were classified as increasing ($b_1 > 0$) or decreasing ($b_1 < 0$) in abundance. Populations were classified as stable if slope did not differ from zero ($b_1 = 0$). Population status of rare species (i.e., occurring in <10% of total collections) and populations of species reported only once were classified as indeterminable. Native status of each species was determined using Conner and Suttkus (1986), Thomas et al. (2007) and Hubbs et al. (2008). Primary and secondary reproductive guilds were determined for each species using the classification scheme of Simon (1999), and trophic guilds after Goldstein and Simon (1999). Mean relative abundance of each species, excluding rare species, for Period I and Period II was determined (sum of relative abundance in each collection/number of collections) to facilitate direct comparison of species abundance between periods. Functional changes within the assemblage were addressed using the relative abundance of each reproductive and trophic guild for each period (sum of individuals in each guild for given period/total individuals in given period).

For each period, taxa richness (S) and Simpson's Index of Diversity ($1 - D$) were calculated along with similarity matrices. Bray-Curtis similarity matrices (Bray and Curtis 1957) created in Primer 6.1.6 were tested with analysis of similarity (ANOSIM; $\alpha = 0.05$; 9,999 permutations) using permutations to assess average rank dissimilarity between periods (Runyan 2007). Data were fourth-route transformed to standardize the contribution of high and low abundance species and illustrated using a multi-dimensional scaling (MDS) plot. Mean relative abundance of MDS axis I and II were averaged for 5-

year intervals to assess trajectory of fish assemblage change. To compare collective trends in increasing or decreasing species through time, relative abundances of increasing and decreasing populations were z-scored transformed to standardized relative abundance distributions (mean = 0; SD = 1) of each species. Z-scored transformed abundances were averaged across all increasing or decreasing species by year (dependent variable) and regressed against time (independent variable) with piecewise regression model. Least-squares regression and joinpoint analyses to detect significant changes in rate through time (i.e., test for appropriate piecewise models) were performed with the program JOINPOINT (Joinpoint Regression Program, Version 3.0, National Cancer Institute, 2005), a program designed to use grid-search methods for optimizing model parameters (Brendon and Bence 2008). Parsimonious joinpoint models were selected following permutation testing ($N = 5,000$; default) rather than BIC selection approach (Brendon and Bence 2008).

RESULTS

Mean annual flows increased between periods in the Guadalupe River and San Marcos River with frequency of small and large flood events increasing only in the upper Guadalupe River and decreasing in the lower Guadalupe River and San Marcos River. Mean annual flow in the upper Guadalupe River (Spring Branch, Texas) increased from $7.27 \text{ m}^3/\text{s}$ in Period I (1927-1964) to $14.04 \text{ m}^3/\text{s}$ in Period II (1965-2007) with annual frequency of small ($95 \text{ m}^3/\text{s}$) and large ($837 \text{ m}^3/\text{s}$) flood events increasing from 0.81 to 1.07 between periods (Figure 1.2). In the lower Guadalupe River, mean annual flow at New Braunfels, Texas, increased from $9.70 \text{ m}^3/\text{s}$ in Period I (1927-1964) to $17.70 \text{ m}^3/\text{s}$ in

Period II (1965-2007) with annual frequency of small ($120 \text{ m}^3/\text{s}$) and large ($949 \text{ m}^3/\text{s}$) floods decreasing from 0.84 to 0.42. Also in the lower Guadalupe River, mean annual flow at Victoria, Texas, increased from $48.10 \text{ m}^3/\text{s}$ in Period I (1938-1964) to $64.01 \text{ m}^3/\text{s}$ in Period II (1965-2007) with annual frequency of small ($569 \text{ m}^3/\text{s}$) and large ($1,461 \text{ m}^3/\text{s}$) floods decreasing from 0.56 to 0.42. In the San Marcos River, mean annual flow at Luling, Texas increased from $9.55 \text{ m}^3/\text{s}$ in Period I (1938-1963) to $13.31 \text{ m}^3/\text{s}$ in Period II (1976-2007) with annual frequency of small ($143 \text{ m}^3/\text{s}$) and large ($490 \text{ m}^3/\text{s}$) floods decreasing from 0.87 to 0.70 (Figure 3).

Fish Assemblage Changes-Guadalupe River

A total of 78 species were reported in the Guadalupe River mainstem (Table 1). Among the 190 collections retained for analysis, 69 species and 41,869 individuals were taken from the Guadalupe River mainstem from 1938 to 2000. Cyprinidae were most abundant (69% in relative abundance), followed by Centrarchidae (11%), Poeciliidae (6%), Percidae (5%), Catostomidae (2%) and Ictaluridae (2%). Among marine-derived taxa, *Mugil cephalus*, *Mugil curema* and *Achirus lineatus* were not considered significant freshwater components of the assemblage. Guadalupe River mainstem assemblage consisted of two basin endemics (*Dionda nigrotaeniata* and *Percina apristis*), disjunct populations of two fishes (*Erimyzon suetta* and *Percina shumardi*), southwestern natural distributional extent, along with the adjacent and connected San Antonio River, of seven species (*Macrhybopsis marconis*, *Fundulus notatus*, *Lepomis humilis*, *Micropterus punctulatus*, *Micropterus treculii*, *Etheostoma chlorosoma*, and *Etheostoma spectabile*),

and 15 introduced species (or 22 introduced species of $N = 78$ fishes reported in the drainage). Relative abundance of introduced fishes was <6% of the total fish assemblage.

Within the upper Guadalupe River, Cyprinidae were most abundant (73% in relative abundance), followed by Percidae (8.1%), Poeciliidae (7.3%), and Centrarchidae (7.1%). Assemblages were similar between Period I (1938 – 1963) and Period II (1965 – 1997). Taxa richness declined from Period I ($S = 42$) to Period II ($S = 41$), and diversity decreased from Period I ($1 - D = 0.86$) to Period II ($1 - D = 0.74$). However, assemblage similarity did not differ between periods (Bray-Curtis index = 37.4%; ANOSIM global R = 0.079, $P = 0.08$). Multi-dimensional scaling (MDS) plot and trajectory plot indicated Period II collections were nested within Period I collections (Figure 4). Despite overall assemblage similarities between periods, population changes were found in 10 taxa. Three cyprinids (*Cyprinella venusta*, *Notropis amabilis*, *Notropis volucellus*), two centrarchids (*Micropterus treculii*, *Lepomis auritus*) and one catostomid (*Moxostoma congestum*) increased in relative abundance, collectively increasing from 30% in Period I to >75% in Period II. Three cyprinids (*Cyprinella lutrensis*, *Macrhybopsis marconis*, and *Pimephales vigilax*) and one percid (*Etheostoma spectabile*) decreased in relative abundance, collectively decreasing from 41% in Period I to <5% in Period II. Two joinpoints were the most parsimonious models for increasing ($P < 0.01$) and decreasing ($P < 0.01$) populations. For increasing taxa, two joinpoints in 1961 denoted two distinct regression models with independent variables ranging from 1938 – 1961 and 1961 – 1997 (Figure 5). Relative abundances were not associated with either time interval ($b_1 \neq 0$, $P > 0.75$). For decreasing taxa, a joinpoint in 1950 and one in 1961 denoted three distinct regression models with independent variables ranging from 1938 – 1950, 1950 – 1961,

and 1961 – 1997. Relative abundance was negatively associated ($b_1 = -0.000259, P < 0.01$) with time period 1950 – 1961.

Within the lower Guadalupe River, Cyprinidae were most abundant (68%), followed by Centrarchidae (13%), Poeciliidae (4.8%), and Catostomidae (3.0%). Differences were found in the fish assemblage between periods. Taxa richness increased between Period I ($S = 40$) and Period II ($S = 62$), and diversity decreased between Period I ($1 - D = 0.92$) and Period II ($1 - D = 0.82$). Fish assemblage similarity differed between periods (Bray-Curtis index = 25%; ANOSIM global R = 0.409, $P < 0.01$). Multi-dimensional scaling plot and trajectory plot indicated that assemblages in Period I were segregated from those of Period II (Figure 4). Differences in the fish assemblages were attributed, in part, to increases in non-native fish occurrences ($N = 13$) between periods and to changes in relative abundances. Three centrarchids (*Lepomis macrochirus*, *L. megalotis*, and *Micropterus salmoides*), one catostomid (*Ictiobus bubalus*) and one clupeid (*Dorosoma cepedianum*) increased in relative abundance, collectively increasing from <4% in Period I to >10% in Period II. Two poeciliids (*Gambusia affinis* and *Poecilia latipinna*), two percids (*Percina carbonaria* and *P. apristis*), one cyprinid (*Notropis buchanani*), and one fundulid (*Fundulus notatus*) decreased in relative abundance, collectively decreasing from 27% in Period I to 6% in Period II. Two joinpoints was the most parsimonious model for increasing populations ($P < 0.01$), whereas one linear regression model (i.e., no joinpoint) was the most parsimonious model for decreasing populations ($P = 0.04$; Figure 5). For increasing taxa, one joinpoint in 1995 and another in 1997 denoted three distinct regression models with independent variables ranging from 1950 – 1995, 1995 – 1997, and 1997 – 2000. Relative abundance

was positively associated ($b_1 = 0.000715, P < 0.01$) with time only during 1995 – 1997. For decreasing taxa without a joinpoint, relative abundance was negatively associated ($b_1 = -0.000063, P < 0.01$) with time during 1950 – 2000.

Fish Assemblage Changes-San Marcos River

Sixty-six species and 58,727 individuals were taken in 94 collections from the San Marcos River from 1938 to 2006 (Table 2). Poeciliidae were most abundant (66%), followed by Cyprinidae (17%), Centrarchidae (10%) and Percidae (<7%). San Marcos River fish assemblage consisted of one endemic (*Gambusia georgei*), three basin endemics (*Dionda nigrotaeniata*, *Percina apristis*, and *Etheostoma fonticola*), disjunct populations of two fishes (*Percina shumardi*, sympatric with those in the Guadalupe River, and *Notropis chalybaeus*), five fishes with southwestern natural distributional extent in the Guadalupe River drainage (*Macrhybopsis marconis*, *Fundulus notatus*, *Micropterus punctulatus*, *Micropterus treculii*, and *Etheostoma spectabile*), and 16 introduced species of fish. Relative abundance of introduced fishes represented <7% of the total fish assemblage. Currently, one species (*Ictalurus lupus*) is reported as extirpated (Kelsch and Hendricks 1990) and another (*Gambusia georgei*) is considered extinct (Miller et al. 1989).

Differences in the San Marcos River fish assemblage were found between Period I (1938 – 1963) and Period II (1975 – 2006). Taxa richness increased between Period I ($S = 48$) to Period II ($S = 58$), and diversity decreased between Period I ($1 - D = 0.91$) and Period II ($1 - D = 0.80$). Fish assemblage similarity differed between periods (Bray-Curtis index = 27%; ANOSIM global R = 0.19, $P < 0.01$). Multi-dimensional scaling plot

and trajectory plot indicated that assemblages in Period I were segregated from those of Period II (Figure 4). Fish assemblage differences were attributed, in part, to increases in non-native fish occurrences ($N = 8$) between periods and to changes in relative abundances. A total of 19 taxa, including one clupeid (*Dorosoma cepedianum*), one catostomid (*Moxostoma congestum*), four cyprinids (*Campostoma anomalum*, *Notropis amabilis*, *N. chalybaeus*, *N. volucellus*), five non-native taxa (*Astyanax mexicanus*, *Hypostomus* sp., *Ambloplites rupestris*, *Lepomis auritus*, *Micropterus dolomieu*), six native centrarchids (*Lepomis gulosus*, *L. macrochirus*, *L. miniatus*, *Micropterus punctulatus*, *M. salmoides*, *M. treculii*), one ictalurid (*Ictalurus punctatus*) and one percid (*Etheostoma spectabile*) increased in abundance, collectively increasing from 13% in Period I to 15% in Period II. Three cyprinids (*Cyprinella lutrensis*, *Macrhybopsis marconis*, and *Pimephales vigilax*), two percids (*Percina carbonaria* and *Etheostoma fonticola*), one ictalurid (*Noturus gyrinus*), and one introduced cichlid (*Cichlasoma cyanoguttatum*) decreased in abundance, collectively decreasing from >48% in Period I to <5% in Period II. Two joinpoints were the most parsimonious model for increasing populations ($P < 0.01$) and one joinpoint was the most parsimonious model for decreasing populations ($P < 0.01$; Figure 5). For increasing taxa, two joinpoints in 1993 denoted two distinct regression models with independent variables ranging from 1938 – 1993 and 1993 – 2006. Relative abundance was positively associated ($b_1 = 0.000021$, $P < 0.01$) with time during 1938 – 1993 and negatively associated ($b_1 = -0.000040$, $P < 0.01$) with time during 1993 – 2006. For decreasing taxa, one joinpoint in 1950 denoted two distinct regression models with independent variables ranging 1938 – 1950 and 1951

– 2006. Relative abundance was negatively associated ($b_1 = -0.000029$, $P < 0.01$) with time only during 1951 – 2006.

Reproductive and trophic guilds changes

Changes in reproductive guilds and trophic guilds were assessed for the lower Guadalupe River and San Marcos River, the two fish assemblages that showed significant assemblage differences between periods according to ANOSIM. Among the 24 fishes with increasing populations through time, reproductive guilds consisted of 59% nest builders, 33% open substrate spawners, and 8% brood hiders; trophic guilds consisted of 54% invertivores, 17% predators, 13% omnivores, 12% herbivores, and 4% detritivores. Among the 13 fishes with decreasing populations through time, reproductive guilds consisted of 30% brood hiders, 23% open substrate spawners, 15% nest builders, 15% internal bearers, and 16% substrate choosers; trophic guilds consisted of 77% invertivores, 15% omnivores, and 8% herbivores.

DISCUSSION

Occurrence and abundance of fishes changed in the Guadalupe River and San Marcos River during a span of about 70 years. During this same time period, characteristics of river discharge were modified; specifically, mean annual flow increased and frequency of small and large flood events generally decreased. Increases in mean annual flows among all three reaches of this study were attributed to computational effects of low water years in 1950s, often described as the drought of record (1949 – 1959; Loaiciga et al. 2000), and to the effects Canyon Lake Reservoir. Discharge during the drought of record represented 25% to 35% of daily discharge records in period I,

lowering the average mean annual flow estimates. Consequently, we suspect that mean annual flows have not meaningfully increased in the upper Guadalupe River or San Marcos River. In contrast, detected increases in mean annual flows are meaningful in the lower Guadalupe River because of water releases at Canyon Lake Reservoir. Canyon Lake Reservoir, operated by US Army Corp of Engineers, regulates discharge releases as part of the reservoir management plan for flood control and recreational activities (Gillig et al. 2001). Likewise, decreases in frequency of small and large flood events were attributed to Canyon Lake Reservoir in the lower Guadalupe River, with effects more noticeable at the nearest downstream Station (08168500). In the San Marcos River, decreases in frequency of small flood events were attributed to flow retarding and retention structures in the San Marcos watershed (Woods and Earl 2002). Interestingly, significant differences in fish assemblage similarities are associated with river reaches that experienced decreases in frequency of small and large flood events (i.e., lower Guadalupe River and San Marcos River).

Fish assemblage changes associated with reductions in frequency of small and large flood events are well documented in temperate and tropical rivers, streams, and small tributaries (Gehrke et al. 1999; Bunn and Arthington 2002; Agostinho et al. 2004; Roy et al. 2005; Mercano-Silva et al. 2006). Reduction in flood frequency affects stream geomorphology, causing a shift toward lentic-type habitat (Poff et al. 1997), contributing to a replacement effect of fluvial specialist with lentic-type, generalist species (Scott and Helfman 2001; Haxton and Findlay 2008). Decreasing abundance of fluvial specialist species occurs through numerous mechanisms, including reduced reproductive success (Durham and Wilde 2006), loss of spawning cues (Bunn and Arthington 2002), barriers

to dispersion (Luttrell et al. 1999) and competitive exclusion from resources (Higgins and Strauss 2008). Subsequent replacement by generalist species occurs through numerous mechanisms as well, including refugia from flood displacement (Steven et al. 2007), fulfillment of void niches (Winston et al. 1991) and increased sedimentation (Poff et al. 1997; Scott and Helfman 2001).

Assemblage changes in the lower Guadalupe River and San Marcos River are consistent with general trends in generalist fish replacements. Within and outside of western gulf slope drainages, generalist fishes are those typically becoming more abundant in areas of flow alterations and include clupeids, some cyprinids, catostomids, poeciliids and centrarchids, whereas fluvial species tend to become less abundant, such as several species of cyprinids, percids and catostomids (Winston et al. 1991; Kingsoving and Bain 1993; Travnichek et al. 1995; Scott and Helfman 2001; Li and Gelwick 2005; Mercado-Silva et al. 2006; Runyan 2007). In this study, abundances of one clupeid, four cyprinids, one catostomid, and 10 centrarchids increased through time in the lower Guadalupe River and San Marcos River. Correspondingly, abundances of fluvial specialist (i.e., 3 percids and 2 cyprinids) decreased through time in the lower Guadalupe River and San Marcos River. Exact mechanisms of these replacements are not known, but likely related to changes in fluvial specialist habitats and reductions in displacement floods as reported in other studies (Valdez et al. 2001; Herbert and Gelwick 2003; Holden et al. 2005; Watson 2006). Effects of displacement floods on generalist fishes were demonstrated by the results of this study. In the San Marcos River, taxa considered increasing from 1938 to 1993, specifically generalist fishes (i.e., *Lepomis auritus*, *Lepomis gulosus*, *Lepomis macrochirus*, *Micropterus salmoides* and *Ictalurus punctatus*),

abruptly decreased from 1993 to 2006. These abundance declines occurred during a period of six large flood events including a catastrophic flood in 1998.

There were inconsistencies with general trends in generalist fish replacements in the lower Guadalupe River and San Marcos River. Poeciliid abundances are expected to increase with decreases in frequency of flood events in western gulf slope drainages (Ward et al. 2003), but they actually decreased through time in the lower Guadalupe River. Similar trends of decreasing abundance through time were observed for *Gambusia affinis* in the San Antonio River (Runyan 2007) and for *Poecilia latipinna* in the upper Guadalupe River (Stevens et al. 2007 and this study). Stevens et al. (2007) suggested that a single flood was responsible for population declines, if not extirpation, of *P. latipinna* in the upper Guadalupe River. As the authors noted, a similar response occurred with another poeciliid during a flood in a Sonoran Desert stream (Collins et al. 1981). Another inconsistency in general trends in generalist fish replacements is that abundances of several fluvial specialists (*N. amabilis*, *N. volucellus*, and *N. chalybaeus*) increased through time, whereas abundances of taxa typically associated with flow altered systems, generalist species with broad tolerances (*Cyprinella lutrensis*, *Pimephales vigilax* and *Etheostoma spectabile*; Matthews 1985; Greenburg 1989; Li and Gelwick 2005; Runyan 2007) decreased through time in the San Marcos River. Similar results were observed in the upper Guadalupe River; *C. lutrensis*, *P. vigilax*, and *E. spectabile* decreased through time, specifically from 1950 through 1961. Based on the timing of abundance declines in these more tolerant taxa in the upper Guadalupe River, we propose that fish collections during the drought of record reflected a stressed system with an abundance of tolerant taxa. With the return of average precipitation and consequently average stream discharge

post 1959, fluvial specialists again proliferated whereas tolerant taxa declined.

Proliferation of the natural fish assemblage does occur in streams once the natural environment returns or is restored, assuming source populations exist and recolonization is not impeded by instream structures (Kinsolving and Bain 1993; Doyle et al. 2005).

Despite alteration of flow regime in the lower Guadalupe River and San Marcos River, fish assemblages within all three reaches of this study remain intact. Relative to streams with similar alteration, the worldwide pattern of loss of diversity and ecosystem function, decline in fluvial specialist abundance and replacement by generalist species are of lower magnitude in the lower Guadalupe River and San Marcos River. For example, the Petit-Saut Dam on the Sinnamary River in French Guiana significantly altered assemblage diversity and trophic structure downstream (de Merona et al. 2005), however we saw few significant changes in trophic structure in the lower Guadalupe and San Marcos rivers. Over-exploitation of water in the Laja River of central Mexico caused significant alteration of assemblage composition with a 20 to 22% increase in exotic species (Mercado-Silva et al. 2006); we found exotics were < 6% within the Guadalupe mainstem and < 7% within the San Marcos River. Our study did not indicate full replacement by generalist species, yet hydrologic alterations in the Virgin-Moapa River System of the southwestern USA resulted in decline of native fish fauna and virtually complete replacement by *C. lutrensis* in some portions (Holden et al. 2005). We attribute changes in the mainstem Guadalupe River to changes in species abundance as well as introduction of exotic species through sportfish stockings in Canyon Reservoir. In the Big Blue River, Kansas habitat generalist species (e.g., *Pimephales vigilax*, *Gambusia affinis*) increased in abundance whereas fluvial specialist species (e.g., *Macrhybopsis*

(*hyostoma*) declined in abundance or become extirpated altogether, and sportfish related activities within impounded portions of the river facilitated introduction of numerous taxa (Gido et al. 2002). Similar to our study, the fish assemblage of the Big Blue River remained relatively stable over the course of 40 years, despite natural inter-annual variation (Gido et al. 2002).

Though the Guadalupe River and San Marcos River fish assemblages remain relatively intact, extinctions, extirpations and introductions have occurred independently and dependently of flow alteration and riverscape fragmentation. Presumed extirpated *Ictalurus lupus* and extinct *Gambusia georgei* of the San Marcos River declined in response to exotic species and sportfish introductions (Miller et al. 1989; Kelsch and Hendricks 1990). Exotic suckermouth catfish in the upper San Marcos River were introduced from the aquarium trade and likely contribute to native taxa decline through competition (Cohen 2008; Cook-Hildreth 2008). Introduction of exotic sportfishes and subsequent bait bucket releases in Canyon Lake Reservoir increased species richness in the Guadalupe River after impoundment. Introduction and proliferation of exotic sportfish and baitfish in the Big Blue River contributed to increased species richness following impoundment, and proliferation of such species was dependent, in part, upon altered flow regime (Gido et al. 2002). Changes more directly coupled to riverscape fragmentation and subsequent flow regime alteration include abundance declines for substrate choosing darters (e.g., *Percina carbonaria* and *P. apristis*) and broadcast spawning minnows (e.g., *Macrhybopsis marconis*). Flow regime alteration of other Western Gulf Slope drainages caused abundance declines for substrate choosers and broadcast spawners following reduction in flood frequencies and subsequent shifts in

habitat availability (Runyan 2007). Riverscape fragmentation is most detrimental to members of the genus *Macrhybopsis* and declines or extirpations related to fragmentation have occurred in Oklahoma (Winston et al. 1991), Arkansas (Luttrell et al. 1999), Kansas (Gido et al. 2002), Texas (Runyan 2007, this study), and Mississippi (Taylor et al. 2008). Concern for future loss of biodiversity in the Guadalupe River and San Marcos River exist for species with limited geographic range (e.g., *Macrhybopsis marconis*, *Dionda nigrotaeniata* and *Etheostoma fonticola*) as well as species of special concern ($N = 7$ Guadalupe River, $N = 7$ San Marcos River; Hubbs et al. 2008).

Knowledge of long-term ichthyological responses to altered flow regime at both the species and assemblage level further improves our ability to predict responses to future threats as well as future conservation plans. For example, Detenbeck et al. (1992) suggested that spawning habitat was a key factor in determining how quickly species recolonize after flood disturbances; specifically, nest-spawning generalist require significantly longer periods for reconlonation. Aarts et al. (2004) and Doyle et al. (2005) found return of spawning habitat after removal of anthropogenic disturbances (e.g., dam removal) was the limiting factor for recolonization of fluvial specialist taxa. Consequently, proposed low-head dam removal on the San Marcos River likely would improve within-stream movement. Poff and Ward (1989) classified the San Marcos River as a perennial flashy system in which floods are important components in determining community structure, and when floods are reduced competitive interactions determine assemblage structure. Such competitive interactions generally result in locally endemic species being out-competed by exotic or introduced species (Rahel 2000), which are numerous in the San Marcos River ($N = 16$; Hubbs et al. 2008). However, the

observed relatively small magnitude of assemblage structure alteration following flood removal from both lower Guadalupe River and San Marcos River is likely explained by the resilient nature of stream fish assemblages (Pearsons et al. 1992).

Table 1.1: Native status, mean relative abundance per time period, population trend and associated P-value, primary and secondary reproductive guild, and trophic guild for species collected in the upper and lower Guadalupe River. Native status was determined by Hubbs et al. (2008) as native (N) or introduced (I). Time period I (1938–1963) represents ichthyological collections leading up to the impoundment of Canyon Reservoir and time period II (1965–2000) after impoundment; ‘X’ indicates rarely reported species. Population trends are increasing (↑), decreasing (↓), stable (S) and indeterminable (-); P-values are reported only for species indicating significant population change. Reproductive guilds follow Simon (1999) and trophic guilds are detritivore (D), herbivore (H), invertivore (IF), omnivore (O), piscivore (P) and planktivore (PL; Goldstein and Simon 1999).

^aSpecies presumed extirpated (Kelsch and Hendricks 1990)^bSpecies presumed extinct (Miller et al. 1989)

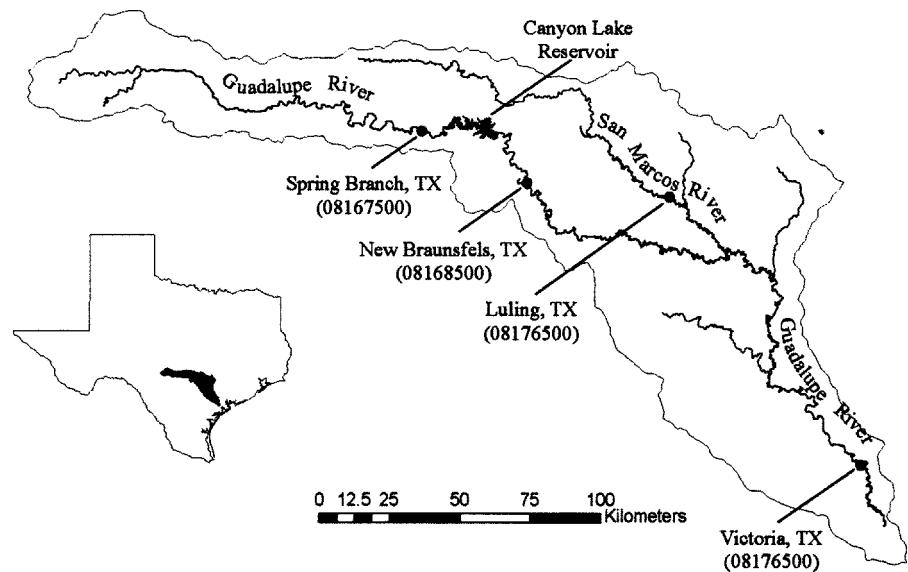

Figure 1.1: Guadalupe River Basin of Texas. Dots represent USGS stream flow gauge locations (station I.D. number) used in Indicators of Hydrologic Alteration (IHA) analysis.

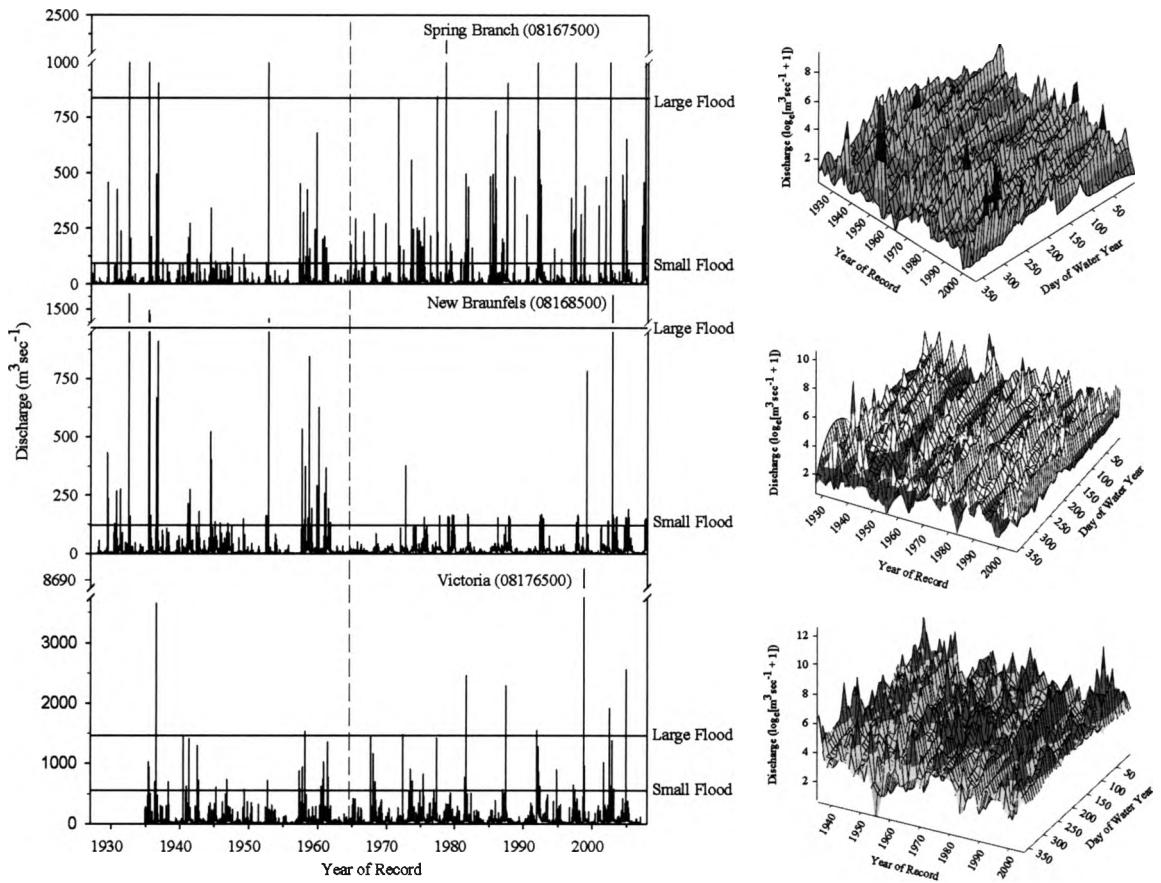

Figure 1.2: Hydrographs and flow histories of the Guadalupe River at Spring Branch, New Braunfels and Victoria, Texas USGS gauging stations. Indicators of Hydrologic Alteration (IHA) was used to assess thresholds and occurrence of large and small floods, vertical dashed line indicates the completion of Canyon Lake Reservoir (1964).

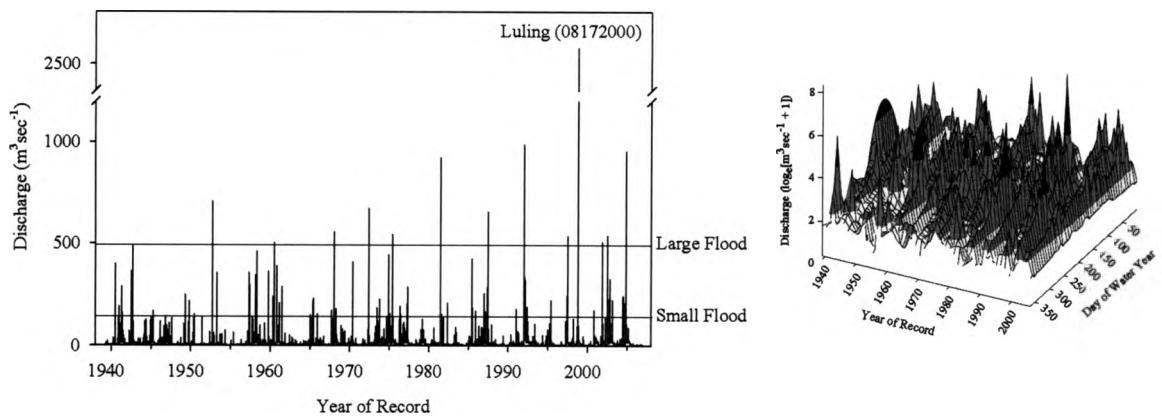

Figure 1.3: Hydrograph and flow history of the San Marcos River at Luling, Texas USGS gauging station. Indicators of Hydrologic Alteration (IHA) was used to assess thresholds and occurrence of large and small floods.

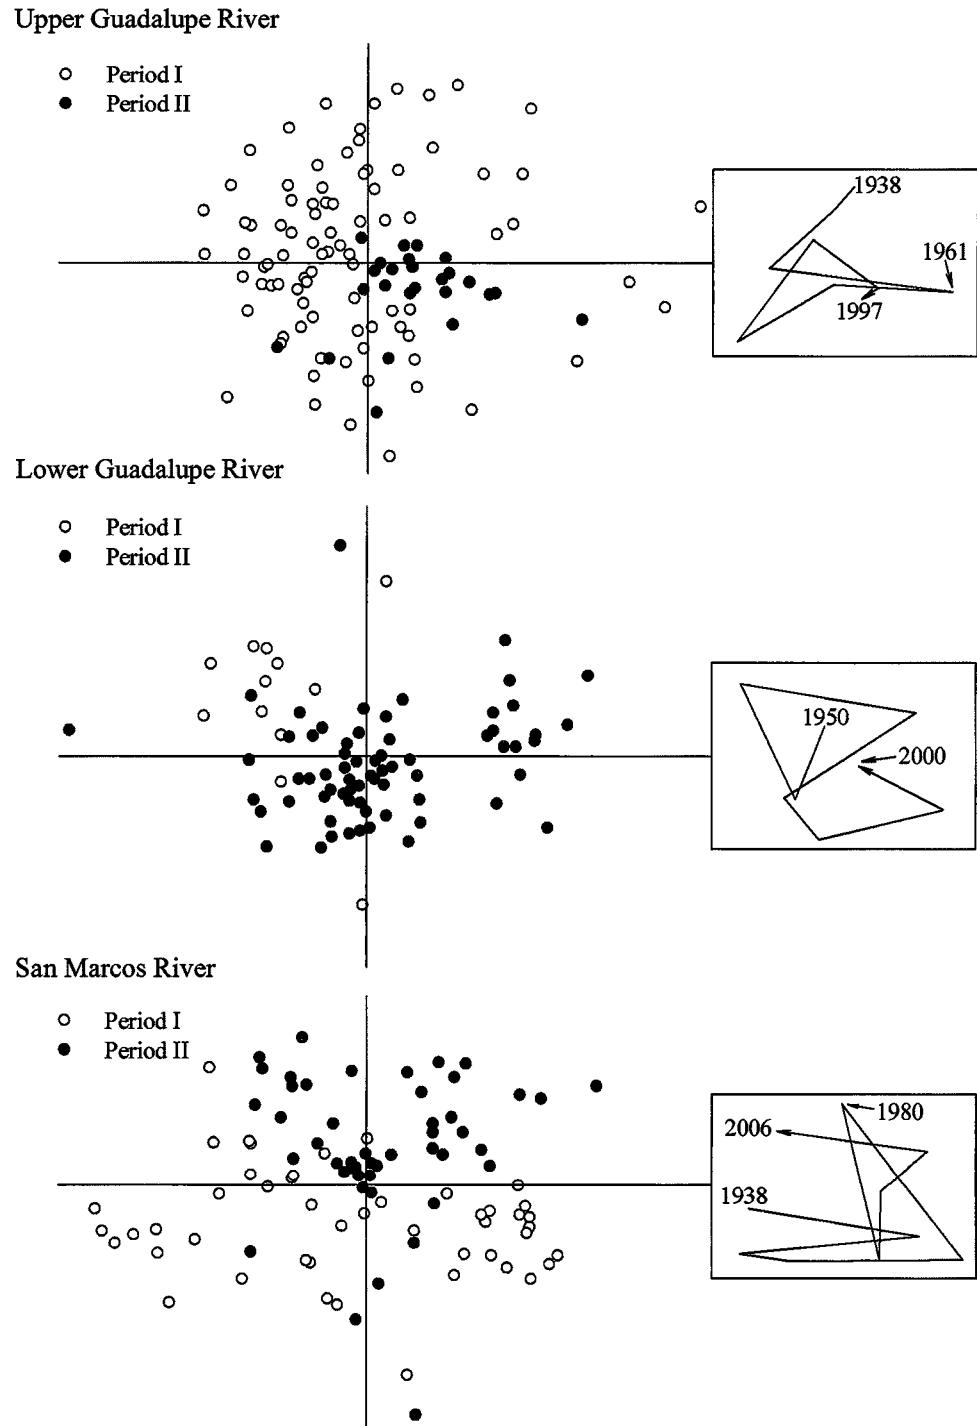

Figure 1.4: Multi-dimensional scaling (MDS) plots and trajectories for upper Guadalupe, lower Guadalupe, and San Marcos River fish assemblages. Points represent ichthyological collections during Period I (open dots) and Period II (closed dots) and are plotted following fourth root transformation of relative abundances; trajectory plots follow 5-year running averages of MDS coordinates.

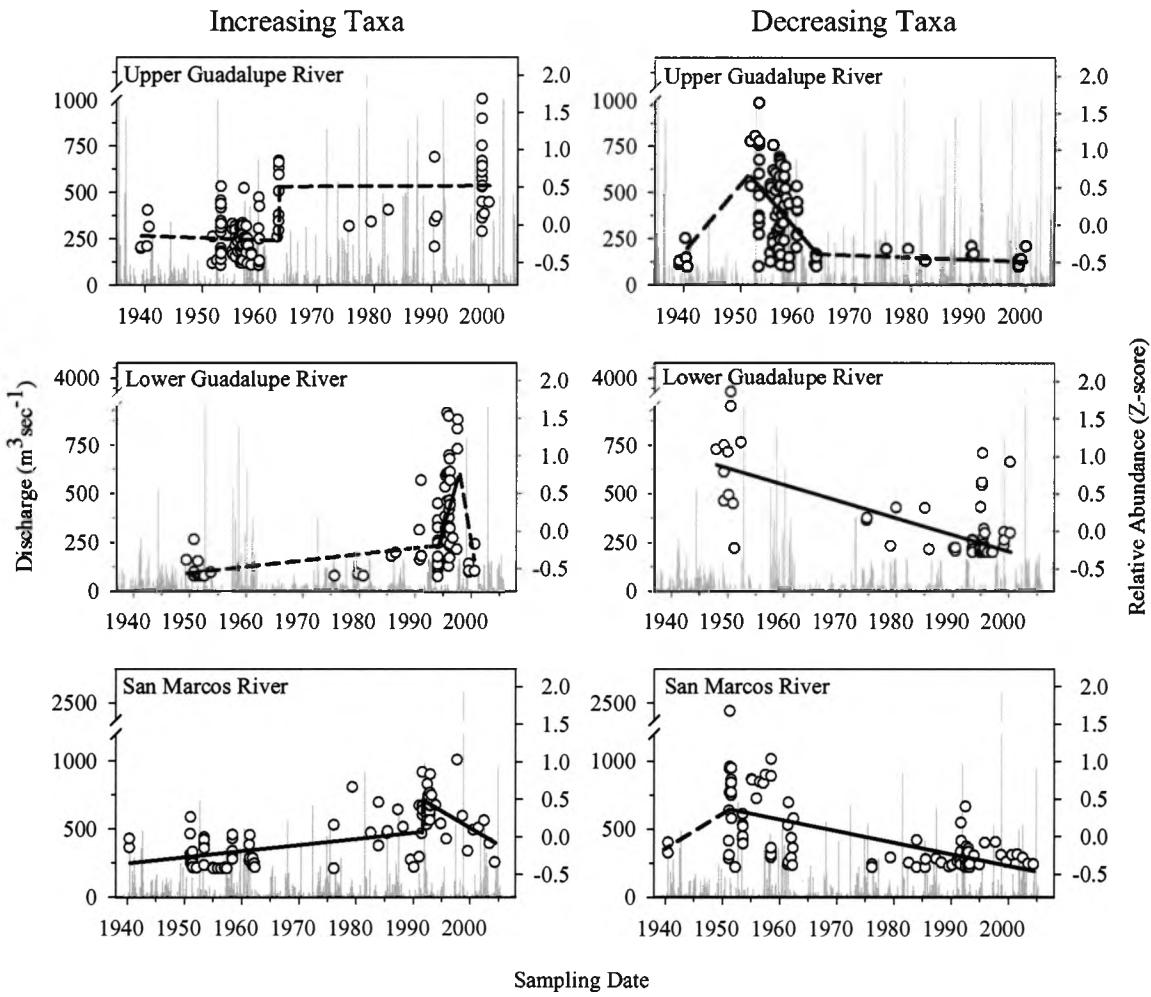

Figure 1.5: Joinpoint regressions for mainstem Guadalupe River and San Marcos River fish assemblages. Open circles represent Z-score transformed mean relative abundance for all species demonstrating significant increasing or decreasing populations. Solid lines indicate significant slopes ($b_1 \neq 0$) and dashed lines indicate non-significant slopes ($b_1 = 0$).

CHAPTER II

MOVEMENT AND MICROHABITAT ASSOCIATIONS OF GUADALUPE BASS *MICROPTEROUS TRECULII* IN THE PEDERNALES AND SOUTH LLANO RIVERS

INTRODUCTION

Movement among refuge, foraging and spawning habitat is crucial to the completion of stream-dwelling fish life history (Schlosser and Angermeier 1995) and is commonly quantified when developing management plans and conservation initiatives for stream-dwelling *Micropterus* species (Horton and Guy 2002; VanArnum et al. 2004). Movement and habitat associations have been considered in the context of sportfish management (Bangham and Bennington 1939) and are well understood for *Micropterus* species with broad distributions and greater sportfish value (i.e., *M. salmoides*, *M. dolomieu*, *M. punctulatus*). Only more recently have movement and habitat use been considered in the context of conservation for imperiled and rare species. Following declining abundance for some species (*M. punctulatus*; Tillma et al. 1998) and imperilment of others (*M. cataractae*, *M. coosae*, *M. treculii*; Warren et al. 2000), a growing body of research has emerged pertaining to the ecological and evolutionary significance of movement and habitat use for stream-dwelling black basses (Horton and Guy 2002; Koppelman and Garrett 2002; Wheeler and Allen 2003; Stormer 2007)

Members of the genus *Micropterus* inhabit lotic systems (Stormer 2007), where habitat specialization has resulted in unique movement and reproductive habitat associations for each species (Koppelman and Garrett 2002). For example, *M. salmoides* spawn on open nests in deep pools and move on the order of kilometers from overwintering to spawning habitats (Mesing and Wicker 1986; Raibley et al. 1997). Conversely, *M. dolomieu* spawn within overhead cover and generally remain within a single mesohabitat during spawning, but may exhibited long migrations (Todd and Rabeni 1989; Lyons and Kanehl 2002; VanArnum et al. 2004). *Micropterus punctulatus* exhibit little movement (e.g., 18 m/h) and generally remain within or close to a single pool, where spawning occurs on gravel bars (Viosca 1931; Horton and Guy 2002). Movement patterns and habitat associations are least understood for regionally endemic black bass species (*M. cataractae*, *M. coosae*, *M. notius*, *M. treculii*; Koppelman and Garrett 2002; but see Wheeler and Allen 2003 and Stormer 2007). Koppelman and Garrett (2002) suggested the paucity of data for the regionally endemic species has resulted in a poor understanding of the competitive adaptations that allow sympatric occurrence of allopatrically evolved species (*sensu* Near et al. 2003). Furthermore, a clear understanding of movement and habitat partitioning may be helpful in understanding consequences of *Micropterus* species introductions (Jackson 2002) as well as how anthropogenic stream regulation influences competition among sympatrically occurring species (Edwards 1980).

Guadalupe bass *M. treculii* is endemic to western gulf slope drainages of central Texas where it is currently listed as a species of *special concern* due to introgression with introduced smallmouth bass and habitat degradation (Hubbs et al. 2008). Whereas

introgression with smallmouth bass represents the most immediate threat to Guadalupe bass persistence, habitat degradation is the most significant threat (Edwards 1980; Garrett 1991). Introgression with smallmouth bass was an unforeseen result of sportfish stockings, and Texas Parks and Wildlife Department (TPWD) currently is combating genetic contamination via supplemental stocking of pure strain, hatchery-produced individuals (Carmichael and Williamson 1986; Garrett 1991; Koppelman and Garrett 2002). Habitat degradation has resulted in localized extirpations and declines in abundance throughout Guadalupe bass range, but specific causes remain poorly understood (Edwards 1978, 1980). Furthermore, despite the longstanding recognition of Guadalupe bass as a stream-adapted species (Hurst et al. 1975), a paucity of data exists pertaining to Guadalupe bass autecology in lotic systems (Garrett 1991).

To date, the ecology, geographic variation, reproduction, diet and mesohabitat associations of Guadalupe bass have been investigated in a single study (i.e., Edwards 1980). Whereas data from Edwards (1980) were relied upon heavily in developing the current management and conservation initiatives for Guadalupe bass (Garrett 1991), microhabitat associations and selection, as well as movement patterns, were not considered by Edwards (1980). A more complete understanding of Guadalupe bass movement patterns and habitat associations will enhance our understanding of why localized extirpations have occurred following habitat degradation, how future land use changes may impact Guadalupe bass habitat, and what microhabitats may be essential for Guadalupe bass life history (*sensu* Orth and Newcomb 2002). The objectives of this study were to (1) determine monthly and diel movement patterns, (2) quantify habitat associations at an ecologically relevant scale, and (3) quantify habitat preference and

suitability for adult Guadalupe bass throughout the primary reproductive period March through June (Edwards 1980).

STUDY AREA

Genetically pure, naturally occurring populations of Guadalupe bass exist in four western tributaries of the Colorado River drainage and the upper portions of the San Antonio River drainage in central Texas (Koppelman and Garret 2002). Specifically, the San Saba River, Pedernales River, Llano River, and Gorman Creek in the Colorado River drainage and the Medina River in the upper San Antonio River drainage remain free of smallmouth bass introductions and large scale habitat alteration (Figure 2.1A). For this study, two sites that are characteristic of streams inhabited by Guadalupe bass were chosen to enhance inferences for streams throughout Guadalupe bass distribution.

The Llano River originates with Edwards-Trinity Aquifer springs emerging and forming the 80 river kilometer (RKM) long North Llano River in Sutton County, and the 89 RKM South Llano River in Edwards County. These branches converge in Kimble County to form the Llano River proper, which continues 161 RKM east through Mason and Llano counties into Lake Lyndon B. Johnson, an impoundment on the Colorado River (Figure 1B). Mean annual discharge at Junction, Texas, just downstream of the North and South Llano rivers confluence, is $7.4 \text{ m}^3 \text{s}^{-1}$ (USGS Gauge 08150000). Guadalupe bass were radio-tagged along a one kilometer stretch of the South Llano River ($30^{\circ}28'7''\text{N}$, $99^{\circ}47'07''\text{W}$). Guadalupe bass movement from the study area was restricted by a low-water crossing at the South Llano River State Park ($30^{\circ}27'0''\text{N}$, $99^{\circ}48'46''\text{W}$)

approximately 4 RKM upstream, and a reservoir at the city of Junction, Texas (30°29'21"N, 99°45'35"W) approximately 4 RKM downstream.

The Pedernales River originates in Kimble County, Texas and flows ~170 kilometers northeastward through Gillespie, Blanco, Hays and Travis Counties and empties into Lake Travis, an impoundment on the Colorado River (Figure 1C). The upper reaches of the Pedernales River rise from spring discharges of the Edwards-Trinity Aquifer, producing a mean annual discharge of $3.4 \text{ m}^3 \text{s}^{-1}$ at Fredericksburg, Texas (USGS Gauge 08152900). Guadalupe bass were radio-tagged throughout a one kilometer stretch of the Pedernales River near Fredericksburg, Texas (30°13'13"N, 98°54'1"W). Guadalupe bass movement from the study area was restricted by a low-water crossing near State Highway 16 crossing (30°12'41"N, 98°56'30"W) approximately 8 RKM upstream, and a low-head dam near Johnson City, Texas (30°17'25"N, 98°23'58"W) approximately 60 RKM downstream.

METHODS

Transmitter Attachment and Tracking

Twelve Guadalupe bass >180 g were collected from each river using electrofishing during December 2007. Radio transmitters (Advanced Telemetry Systems Model F1580) with 250 day battery life were surgically implanted following the anesthetization methods of Peake (1998; 60 mg/L) and surgical methods of VanArnum et al. (2004). To improve retention, tag antennae were inserted through a small puncture made 10 to 15 mm behind the incision using a modified hypodermic needle (Stormer 2007). Fish were released at the site of collection after regaining equilibrium and normal

swimming ability, and a period of seven days was given for fish to adjust to added weight of radio transmitters (i.e., 3.6 g, <2% body weight; Winter 1996) before tracking was conducted January 6, 2008 through August 16, 2008. Three element, handheld directional yagi antennae (Advanced Telemetry Systems) and Lotek Model SRX 400 (150 MHz) radio receivers were used to track Guadalupe bass by walking shoreline in shallow areas and from kayak in deep areas. Triangulation techniques and visual observation from shoreline and by snorkeling (Winter 1996) improved radiolocation accuracy. When radio signals were not detected within a given river, multiple kayak passes were conducted from upstream to downstream boundaries.

Movement and Habitat Associations

Tracking during daylight hours was conducted bi-weekly, roughly every 11 to 16 days, throughout the study (Horton et al. 2004). Diel movement and habitat associations were assessed on a subset of individuals ($n = 5$) in the Pedernales River by conducting hourly tracking for a period of 15 to 24 consecutive hours on three evenly distributed occasions: March, May, July (Todd and Rabeni 1989). Bi-weekly and diel movements were analyzed independently (Horton et al. 2004) as the linear distance moved since the last tracking session (Stromer 2007). Movement patterns of individuals were classified as sedentary (those that remained within the original capture mesohabitat), upstream, and downstream, and maximum distances moved were measured from the original capture site (VanArnum et al. 2004). Upon each relocation, we recorded Global Positioning Satellite (GPS) coordinates (Trimble model XH units with sub-meter accuracy), water

temperature (°C), current velocity (m/s), depth (m), mesohabitat, dominate substrate, and instream cover or distance to cover (Table 2.1).

Habitat Availability

We determined habitat suitability by calculating the proportion of habitat used from tracking observations in ratio to the total available habitat. Traditional transect sampling methods (Simonson et al. 1994) were inadequate for estimating distribution and availability of all cover types (i.e., large woody debris and undercut banks) in our study streams. Thus, we utilized a novel approach to mapping and modeling available habitat over a representative stretch of each river (i.e., 40x mean channel width; Simonson et al. 1994). Trimble model XH units were used to delineate polygons of available cover, mesohabitat and dominate substrates within our study areas. Standard survey equipment was used to measure topography within the annual wetted channel of each study site by using a stratified random sampling design that incorporated all available heterogeneity in topography. Latitude (X), longitude (Y), topography (Z) and dominate substrate (roughness) were recorded in Trimble data dictionaries for each point surveyed. Water surface elevation (WSE) was recorded longitudinally for each river, encompassing changes in WSE at each mesohabitat (i.e., at the upstream and downstream point of each). Survey data (X, Y, Z; roughness) and WSE data were loaded in Multi-Dimensional Surface-Water Modeling System (MDSWMS; McDonald et al. 2001) to model distribution and availability of current velocities and depths following the methods of Barton et al. (2005). Two-dimensional solution files for depths and current velocities were exported from MDSMWS and overlaid with cover, substrate, and mesohabitat

polygons in ArcView 9.2 to yield spatially explicit layers of mapped sections for each river.

Data Analyses

Sample sizes for all statistical analyses were calculated as the number of individuals for which ≥ 12 radiolocations were obtained over the course of the study; individuals with < 12 radiolocations were removed from analyses. Distances moved during bi-weekly and diel tracking were analyzed using ArcView 9.2 (Environmental Systems Research Institute 2007). Mean monthly movement (m/d) was calculated as the grand mean of all individual mean movements within a given month (VanArnum et al. 2004). Mean diel movement (m/h) was calculated in a similar fashion, but mortality of three fish, and subsequent inclusion of three different fish, by July precluded a repeated measures analysis of diel movement across months. As a result, only mean ($\pm SD$) movement rates are reported for diel movements. To assess associations with movement, factors commonly identified with black bass movement (i.e., water temperature, calendar day number, flow rate and reproductive season; Railsback et al. 1999) were ordinated using principal components analysis (PCA; CONOCO 2002). Magnitude of grand mean movement for each month was included in the PCA biplot to illustrate factors associated with greater magnitudes of Guadalupe bass movement. Bi-weekly habitat observations were ordinated using PCA to assess changes in habitat associations during the study. Grand mean monthly PCA scores were calculated for each river to illustrate changes in habitat associations through time. Observed habitat associations collected during diel tracking were ordinated using PCA and diel times were included in the PCA biplot to

illustrate habitat associations during day and night. For PC analyses, qualitative variables (i.e., reproductive season, cover, mesohabitat, substrate, and river) were represented by dummy variables and quantitative variables (i.e., temperature, day number, flow, distance to cover, depth and velocity) were z-score transformed (Williams and Bonner 2006).

Univariate statistical analyses were used to assess cover, substrate and mesohabitat preference or avoidance as well as habitat suitability for current velocity and depth by considering observed usage versus total available habitats. Total availability of cover types was calculated as the area (m^2) of polygons for each cover type within the mapped region of each river. Total availability of substrate classes was calculated using data collected during stratified random sampling of each river. Total available mesohabitat was calculated as the area (m^2) of polygons for each mesohabitat within the mapped region of each river. For cover, substrate and mesohabitat, the number of observations within a given class were figured for each individual and averaged across individuals to yield mean percent use. Preference or avoidance of cover, substrate and mesohabitat were determined using the electivity index of Jacobs (1974), where 1 indicates complete preference and -1 indicates complete avoidance (Stormer 2007). Habitat suitability was calculated using all observations of Guadalupe bass associations with current velocities and depths, including observations made during diel hours for individuals in the Pedernales River. Bin widths of suitability curves were determined using the Sturges (1926) equation for all available depths and velocities (extracted from MDSWMS) and use versus availability were plotted (Newcomb et al. 2007).

RESULTS

Lengths of radio tagged Guadalupe bass ranged 320 – 480 mm total length (TL) in the South Llano River and 260 – 373 mm TL in the Pedernales River. Twenty-two of the 24 radio tagged Guadalupe bass survived greater than five months for a minimum of 12 relocations per fish and were retained for statistical analysis. Two individuals excluded from analysis were radio tagged in the South Llano River. One shed tag was found downstream in February and the other was not relocated after March. Among the 22 tagged fish, 17 fish survived and five fish died (May $n = 1$, June $n = 2$ and July $n = 2$) by the end of the study period in August 2008. Causes of mortality included angler harvest ($n = 1$), predation by a large flathead catfish *Pylodictis olivaris* ($n = 1$), avian predation ($n = 2$) and undetermined ($n = 1$).

Monthly and Diel Movement

Among the 22 fish, 13 were sedentary (mean \pm SD distance from capture site = 16.6 ± 24.1 m), six moved upstream ($1,026.8 \pm 425.5$), and three moved downstream ($1,539.0 \pm 1641.3$). Five of the upstream movements (max. distance = 1,472 m) occurred in the Pedernales River during June. Only one fish moved upstream 627 m in the South Llano River during April. Three fishes moved downstream (max distance = 3,420 m) in the South Llano River during April.

Mean monthly movements ranged from < 1 m/d to 9 m/d and were primarily associated with reproductive season. The first two principal component axes (PCA) explained 82% of total variation in factors generally associated with black bass movement (Table 2.2). The first PCA (56% of total variation) represented a temperature,

day number, and flow gradient (Figure 2.2). Months with highest negative loadings along PCA I were characterized by higher mean temperatures (loading = -1.29) and greater day number (Julian date; -1.23), whereas months with high positive loadings were characterized by higher mean monthly flow (0.86). The second PCA (26%) primarily represented a reproductive period gradient. Months with highest negative values along PCA II were characterized by reproductive season (-1.89). Fish movement was not associated with PCA I ($r = 0.17, P = 0.51$) and positively associated with PCA II ($r = 0.77, P < 0.01$), specifically reproductive season. Increases in movement rates were correlated with increases in temperature until maximum movement rates occurred (Jan-Apr, South Llano River $r = 0.98, P < 0.01$; Jan- Jun, Pedernales River $r = 0.97, P < 0.01$).

Diel movements ranged from 0 to 35 m/h during the day and from 0 to 45 m/h during the night. Mean (\pm SD) movement rate (m/h) during the day was 3.54 (\pm 3.21) in March, 16.30 (\pm 16.35) in May, and 5.28 (\pm 7.57) in July. Mean (\pm SD) movement rate during the night was 6.35 (\pm 9.28) in March, 13.67 (\pm 16.08) in May, and 5.49 (\pm 6.30) in July.

Habitat Associations

The first two PC axes explained 30% of total variation in available habitats within the South Llano River and Pedernales River (Table 2.2). The first PCA (18% of total variation) represented a velocity, depth and substrate gradient (Figure 3). Habitats with high negative loadings along PCA I were characterized by run mesohabitats (-1.57) with swift current velocity (-1.52) over course gravel substrate (-1.11). Habitats with high positive loadings along PCA I were characterized by pool mesohabitats (1.86) with silt

substrate (1.66) and greater depths (1.47). The second PCA (12%) represented primarily a cover gradient. Habitats with high negative loadings along PCA II were characterized by greater distances from cover (-1.65) and great depths (-1.01) over cobble substrate (-0.82). Habitats with high positive loadings along PCA II were characterized by instream cover (2.21) over bedrock substrate (1.48) in backwater mesohabitats (1.40). Among available habitats, Guadalupe bass were relocated among several mesohabitat types, depths, current velocities, and substrates (Figure 2.3A). Grand mean (i.e., all fish combined) PCA scores of habitat associations were near the origin of PCA I, split between run and pool mesohabitats in the South Llano River (mean \pm SD = -0.06 ± 0.248) and positive, towards pool mesohabitats in the Pedernales River (0.19 ± 0.306 ; Figure 3B). Grand mean PCA scores of habitat associations were positively associated (0.16 ± 0.186 South Llano River; 0.19 ± 0.263 Pedernales River) with PCA II, towards instream cover. Plotting trajectory of mean PCA scores by month and across individual fish, associations with cover and bedrock substrates were stronger in the winter (pre-reproductive season) in both rivers, thereafter associations were with greater distances from cover and greater depths (Figure 2.3C). With the onset of the reproductive season (March through June), trajectories moved negatively along PCA I for the South Llano River and positively along PCA I for the Pedernales River. Contrasting shifts along PCA I generally corresponded with declining flows in the Pedernales River (Figure 2.4).

For diel habitat associations, the first two PCA axes explained 38% of total variation in available habitats in the Pedernales River (Table 2.2). The first PCA axis (22% of total variation) represented a mesohabitat, velocity and cover gradient. Mean PCA scores with high negative loadings for PCA I were characterized by silt substrate (-

1.63) and instream cover (-1.25) in pool mesohabitats (-1.09; Figure 2.5). Mean PCA scores with high positive loadings for PCA I were characterized by higher current velocities (1.76) in run mesohabitats (1.51) with cobble substrate (1.41). The second PCA axis (16%) represented a mesohabitat, cover and depth gradient. Mean PCA scores with high negative loadings for PCA II were characterized by instream cover (-1.62) in backwater mesohabitats (-1.58) over bedrock substrate (-0.97). Mean PCA scores with high positive loadings for PCA II were characterized by pool mesohabitats (1.80) with greater distances from cover (1.79) and greater depths (1.50). Diurnal and nocturnal observations of individuals were generally split along a diagonal gradient from positive PCA I to positive PCA II. Diurnal observations were generally negative along PCA I and II, and were characterized by instream cover in backwaters or pools over silt or bedrock. Nocturnal observations were generally positive along PCA I and II, and were characterized by either pool mesohabitats with greater depths or run mesohabitats with greater velocities, but overall distances from cover were greatest during nocturnal hours. Nocturnal associations with run mesohabitats dominated observations in March, but a gradual shift toward pool mesohabitats occurred in May and July.

Guadalupe bass habitat use varied in comparison to availability among univariate gradients. Open water constituted > 90% of available habitat in both rivers, but mean percent use across fish indicated open water was avoided (Jacobs electivity < -0.9 for both rivers; Figure 2.6). Jacobs electivity values were > 0.7 for all instream cover types except vegetation, which was the least available cover in the Pedernales River (< 0.1%) and was not used, resulting in a Jacob's electivity value of -1. Electivity values were positive for silt, sand, fine gravel and coarse gravel in the South Llano River, and silt,

course gravel and bedrock in the Pedernales River (Figure 2.7). Electivity values were positive for backwater and eddy in the South Llano River, and pool, backwater, and eddy in the Pedernales River. Available depths ranged 0 – 6 m, and suitability was highest (1.0) for 1.0 m depth in both rivers, and use was correlated with availability for depths > 1.0 m (South Llano River $r = 0.90$, $P < 0.01$; Pedernales River $r = 0.88$, $P < 0.01$; Figure 2.8). Available velocities ranged 0 – 0.6 m/s, and suitability was highest (1.0) for 0.05 m/s in both rivers, and use was correlated with availability for velocities > 0.05 m/s (South Llano River $r = 0.91$, $P < 0.01$; Pedernales River $r = 0.97$, $P < 0.01$), although observed values of velocity were consistently less than available in the South Llano River.

DISCUSSION

Guadalupe bass were associated with eddy mesohabitats created by instream cover within or adjacent to run mesohabitats, small to medium size substrates, 1.0 m depths, and <0.1 m/s current velocities. Log complexes, boulders, and ledges were used often, whereas open water generally was avoided. Microhabitats used by Guadalupe bass in this study are similar to those reported for other stream-dwelling *Micropterus*. Smallmouth bass in rivers are associated with large woody debris and boulders, depths ranging from 1 to 2 m, current velocities <0.2 m/s, and avoid open water during daylight hours (Todd and Rabeni 1989; Orth and Newcomb 2002). Spotted bass and shoal bass are associated with eddy mesohabitats, depths ranging 0.4 – 1.4 m, current velocities < 0.35 m/s, and preferred boulder cover types while avoiding open water (Horton and Guy 2002; Stormer 2007).

Movement patterns of Guadalupe bass during eight months of tracking ranged from within mesohabitat to 3.4 km from point of initial capture. Among 22 fish, 13 bass moved < 58 m and remained within mesohabitats of initial capture, whereas nine bass moved into other mesohabitats with similar microhabitats. *Micropterus* in streams and rivers are primarily sedentary (movement < 1.6 km; Funk 1957), but more mobile individuals of largemouth bass and smallmouth bass travel up to 24 km (Funk 1957; Raibley et al. 1997; Lyons and Kanehl 2002; VanArnum et al. 2004). Intraspecific variation in movement is known for several riverine-type fishes (Funk 1957; Gerking 1959; Hill and Grossman 1987; Gatz and Adams 1994; Smithson and Johnston 1999) and likely attributed to biotic (i.e., genetics, ontology, population size) and abiotic (i.e., habitat availability and suitability, spates, drying) conditions (Funk 1957; Raibley et al. 1997; VanArnum et al. 2004; Stormer 2007; Remshardt and Fisher 2008; Cooke et al. 2008).

Habitat associations and movement patterns of Guadalupe bass were influenced by season. During winter, habitat associations were narrow and movement rates ranged < 1 – 3 m/d. During spring and the reproductive season, habitat associations were broader and movement rates ranged 3 – 9 m/d. During late summer, habitat associations were narrow and movement rates ranged < 1 – 3 m/d. Inhabiting undercut banks or instream covers requires minimal energy expenditure for abiotic (e.g., current velocity) or biotic (e.g., vigilance) conditions during the winter at a time with low prey availability (Edwards 1980; Raibley et al. 1997; Allouche 2002). Daily movements from winter into spring typically increase > 200% in *Micropterus* and are related to foraging activities and reproduction (Edwards 1980; Mesing and Wicker 1986; Todd and Rabeni 1989; Horton

and Guy 2002; Stormer 2007). Consequently, habitat associations are more general and home range sizes increase during the spring (Todd and Rabeni 1989; Raibley et al. 1997). Regardless, Guadalupe bass, like many other stream-dwelling fishes (Schlosser and Angermeier 1995), were not involved in long-range spawning migrations.

Additional environmental factors related to Guadalupe bass movement, and consequently habitat associations, were time of day and flow regime. Guadalupe bass often shifted from within cover habitats during the day to open water during the night. Associating with cover during the day likely reduces predation risks for the Guadalupe bass (Horton and Guy 2002), and movement into open water is likely for nocturnal foraging (Todd and Rabeni 1989). In addition to diel movements, Guadalupe bass were readily responsive to changes in the flow regime. During the May 2008 diel tracking period, Guadalupe bass in the Pedernales River shifted from branches and roots along the stream bank to downstream of boulders or bedrock ledges during a rapid rise in flows caused by a flash flood event. Use of instream structure as refugia is suspected in stream-adapted fishes (Minckley and Mefee 1987) to resist downstream displacement. To date, telemetry studies only tracked smallmouth bass to eddy mesohabitats with lower current velocities during a flood event (Todd and Rabeni 1989). Also in the Pedernales River, Guadalupe bass gradually shifted towards pools with greater depths during a period of extreme low flow in summer. Fish responding to periods of stream drying by moving from preferred habitats is common in stream fishes (Matthews 1996) and *Micropterus* (Stormer 2007).

Habitat degradation is the most significant threat to Guadalupe bass persistence (Edwards 1980). Herein, Guadalupe bass habitat for individuals >260 mm in TL

consisted of a heterogeneous mix of run and open water pool habitats with undercut banks and instream woody debris. Extirpation of the Guadalupe bass in the Concho River of Texas (Edwards 1980) is likely attributed to changes in available habitats because of dam construction, in which flood pulses, undercut banks, habitat heterogeneity, and deposition of large woody debris are typically reduced (Poff et al. 1997; Crook and Robertson 1999). Similar habitat changes attributed to dam construction and mismanagement of watersheds likely caused population declines and localized extirpations in shoal bass (Stormer 2007). Future concerns for Guadalupe bass persistence include stream dewatering (Hurst et al. 1975) and aquifer drawdown (Bowles and Arsuffi 1993) as well as localized extirpations following impoundment (Edwards 1978) and competition with lacustrine-adapted species (Koppelman and Garrett 2002), all of which may contribute to reduction of Guadalupe bass range (Jelks et al. 2008). Such negative impacts associated with anthropogenic stream alteration occur worldwide and may be mitigated by watershed management practices that favor sustainable management and ecological integrity (Richter et al. 2003).

Table 2.1: Habitat parameters measured or modeled for Guadalupe bass in the South Llano River and Pedernales River.

Parameter	Description
Temperature	Water temperature measured in °C
Velocity	Current velocity measured in m/s
Depth	Maximum depth measured in m
Mesohabitat ¹	
Run	Moderate depth, moderate to swift current and dominated by bedrock or boulder substrate
Riffle	Shallow depth, moderate to swift current and dominated by gravel or cobble substrate
Pool	Greater depth, little to no current and dominated by silt or sand substrate
Eddy	Moderate depth, circular flow near run or riffle
Backwater	Moderate to shallow depth, little current and within instream cover
Substrate ²	
Bedrock	Unbroken stream bottom
Silt	Small particles less than 0.6 mm
Sand	Diameter between 0.6 and 2mm
Small Gravel	Diameter between 2 and 16 mm
Course Gravel	Diameter between 16 and 64 mm
Cobble	Diameter between 64 and 256 mm
Boulder	Diameter between 256 and 4096 mm
Instream Cover ³	
Log	A single log with large diameter
Log Complex	Two or more logs forming a single structure
Branches	Submerged branches or branches extending into the water
Vegetation	Submerged or emergent aquatic vegetation
Roots	Roots of deposited large woody debris or associated with bank overhang
Undercut Bank	Eroding or over hanging banks (without roots present)
Boulder/Ledge	Crevices of large boulders and ledges formed by bedrock outcroppings
Open Water	Water >0.33 m deep with no cover immediately adjacent
Distance to Cover	Linear distance to nearest cover measured in m

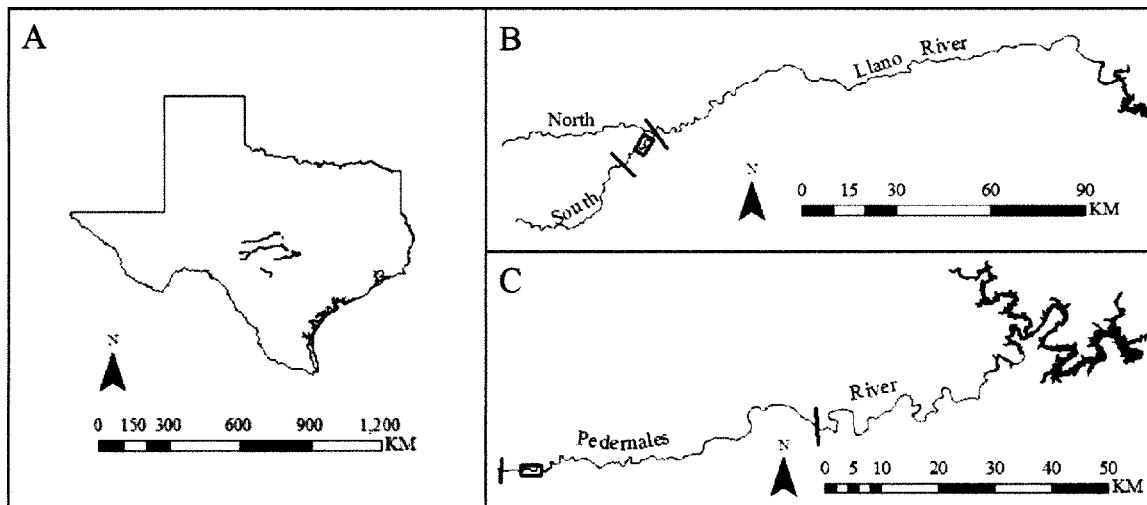

Figure 2.1: (A) Current distribution of naturally occurring, genetically pure Guadalupe bass populations, streams are (North to South): San Saba River, Gorman Creek, Llano River, Pedernales River, and Medina River (Koppelman and Garrett 2002); (B) Study site (indicated by rectangle) and physical barriers (solid lines) on the South Llano River; (C) Study site and physical boundaries for Pedernales River; see text for descriptions of physical barriers.

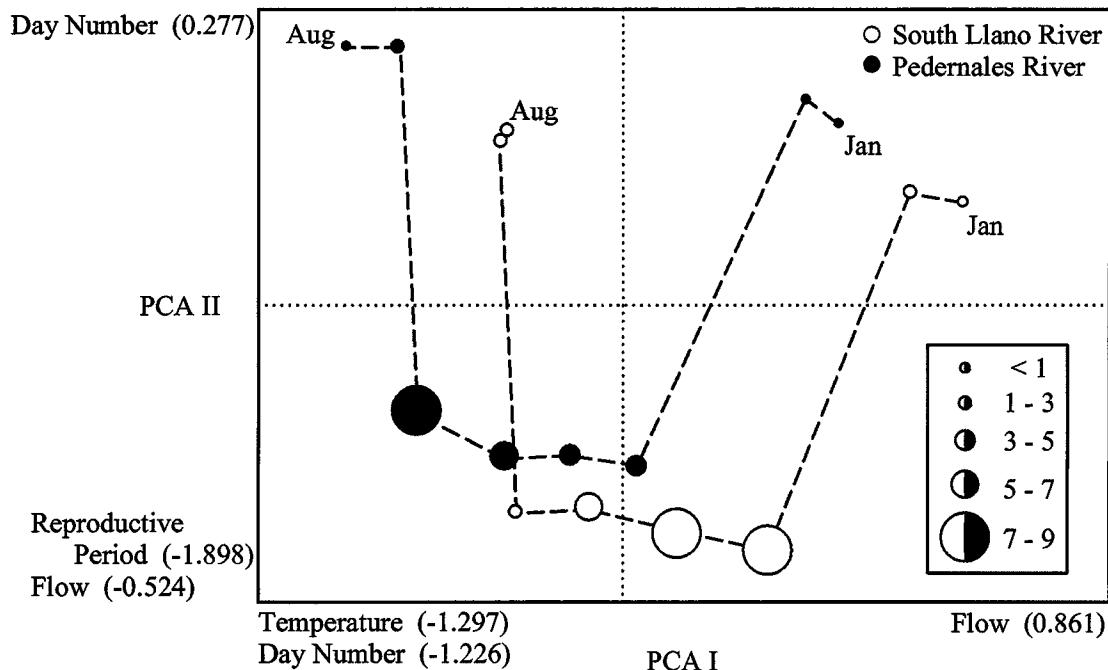

Figure 2.2: Biplot of principal component axes (PCA) I and II for factors associated with mean monthly movement (m/d) of Guadalupe bass in the South Llano River (open circles; $n = 10$) and Pedernales River (closed circles; $n = 12$) January through August 2008. Diameter of circles corresponds with monthly movement rates (m/d) shown in legend. Numbers in parentheses indicate loadings for each parameter.

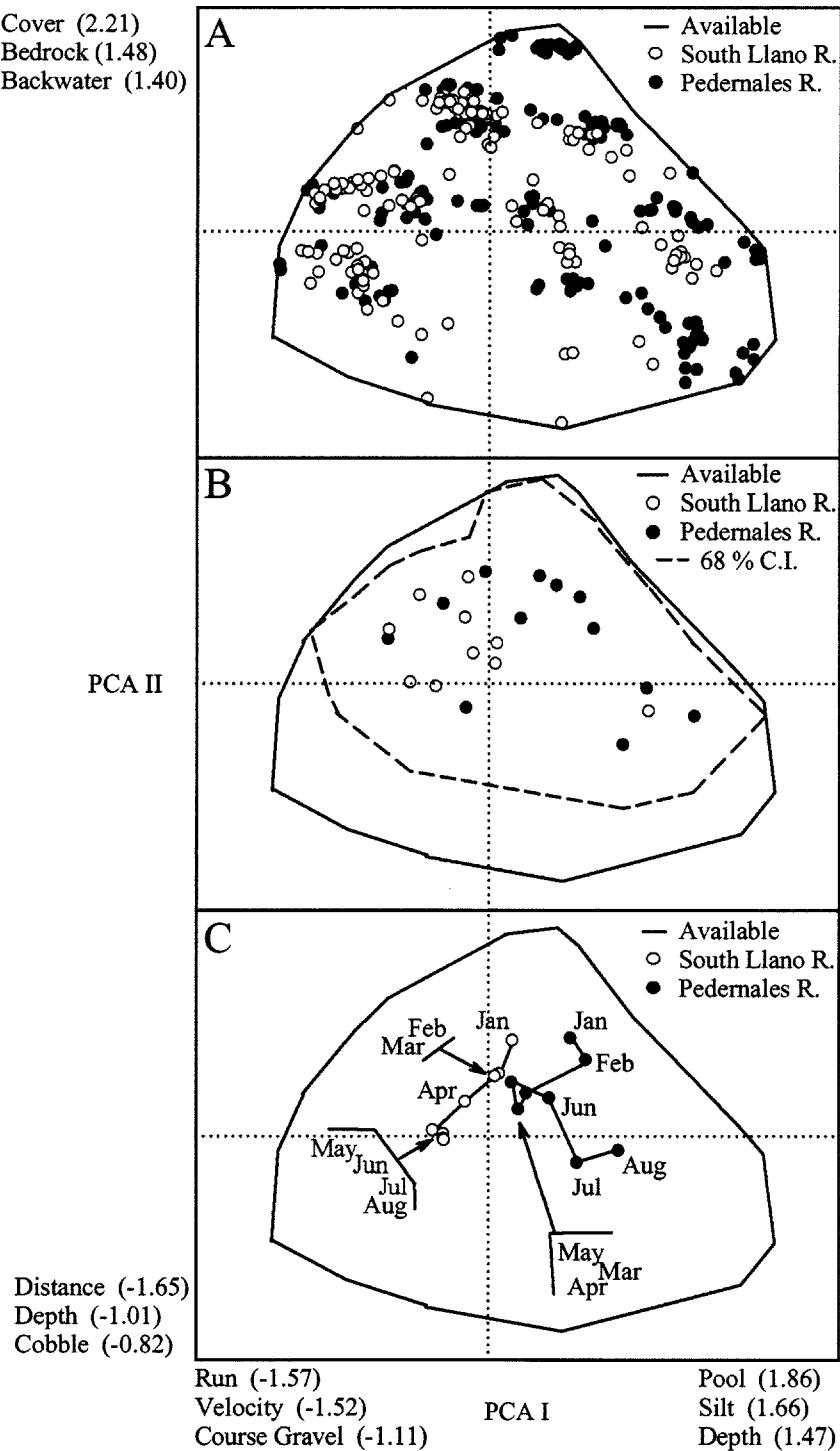

Figure 2.3: Biplots of principal component axes (PCA) I and II for: (A) all available habitat (solid line) and all observations in the South Llano River (open circles) and Pedernales River (closed circles); (B) mean PCA scores per individual (circles) and 68% confidence interval (dashed line) of locations; (C) monthly mean (grand mean of all individuals) PCA scores for 22 Guadalupe bass tracked January to August 2008. Numbers in parentheses indicate loadings for each parameter.

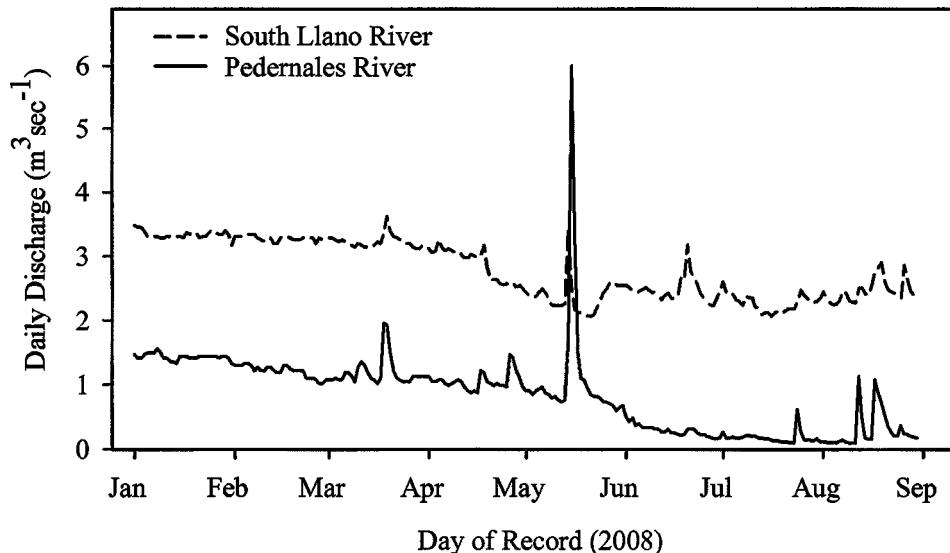

Figure 2.4: Daily discharges for the Pedernales River near Fredericksburg, TX (USGS Gauge I.D. 08152900) and South Llano River near Junction, TX (USGS Gauge I.D. 08150000 – 08148500). Daily discharges for the South Llano River were inferred from North Llano River (USGS 08148500) and Llano River proper (USGS 08150000) discharges measured at Junction, TX.

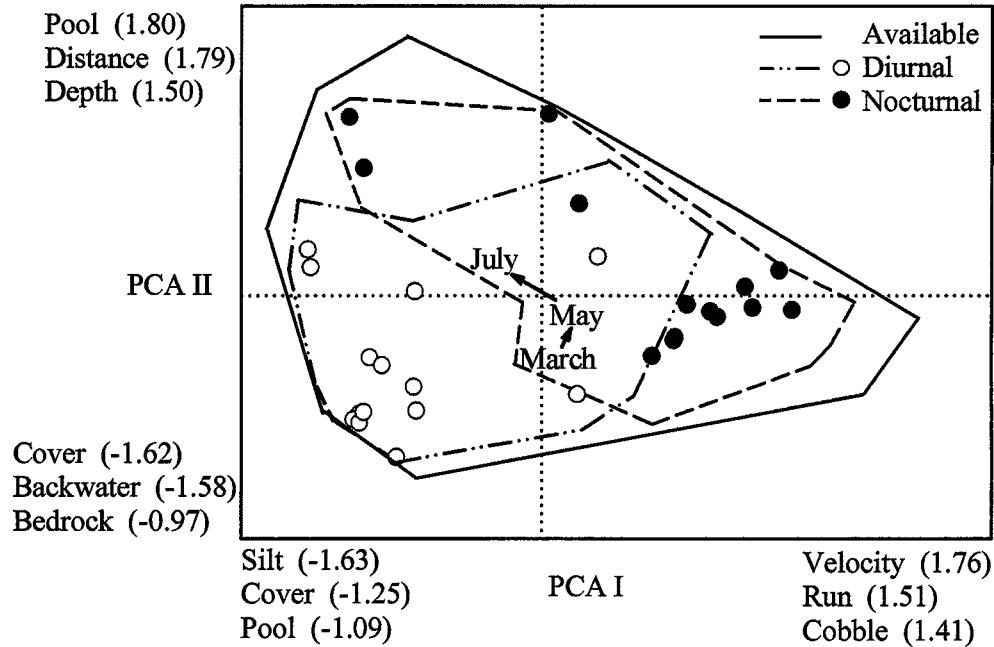

Figure 2.5: Biplot of principal component axes (PCA) I and II illustrating all available habitat (solid line), mean PCA scores and 68% confidence interval of individuals observed during daylight (diurnal; open circles, dash-dot-dot line) and nighttime (nocturnal; closed circles, dashed line) hours in the Pedernales River near Fredericksburg, TX during March, May, and July 2008. “March”, “May”, and “July” indicate mean PCA scores of all individuals tracked for that month (includes diurnal and nocturnal). Numbers in parentheses indicate loadings for each parameter.

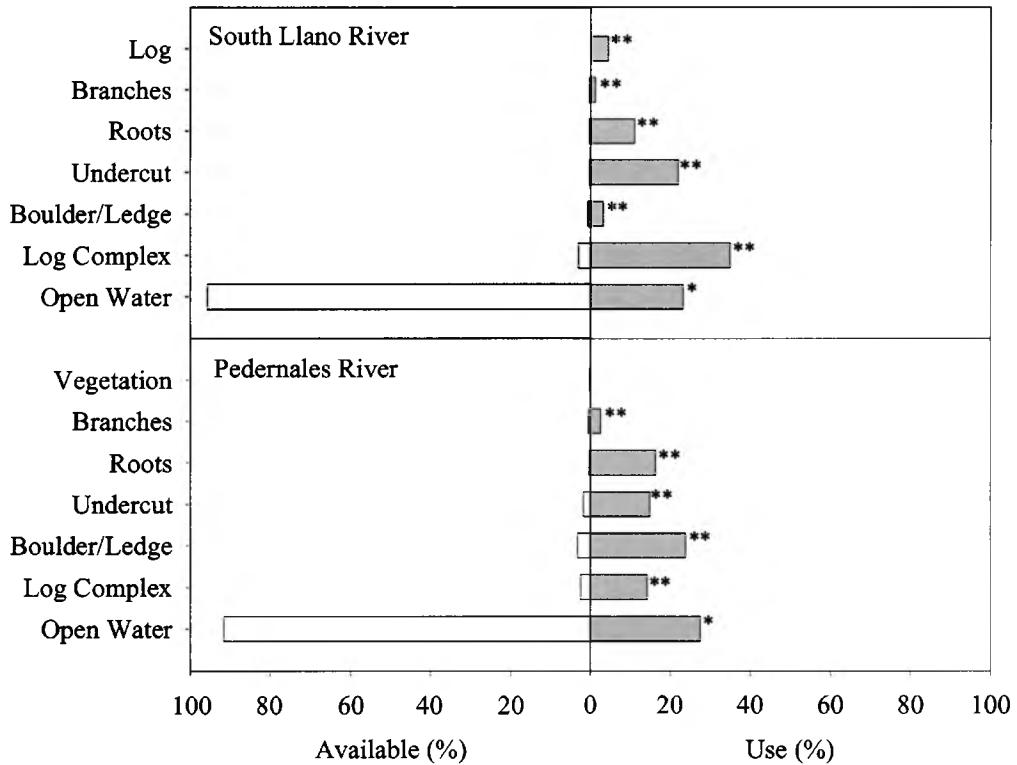

Figure 2.6: Percent frequency occurrence of available habitat (white bars) and mean percent use (grey bars) in the South Llano River and Pedernales River for 22 Guadalupe bass tracked January through August 2008. One asterisk indicates avoidance: Jacob's electivity value < -0.9 ; two asterisks indicate preference: Jacob's electivity value > 0.7 .

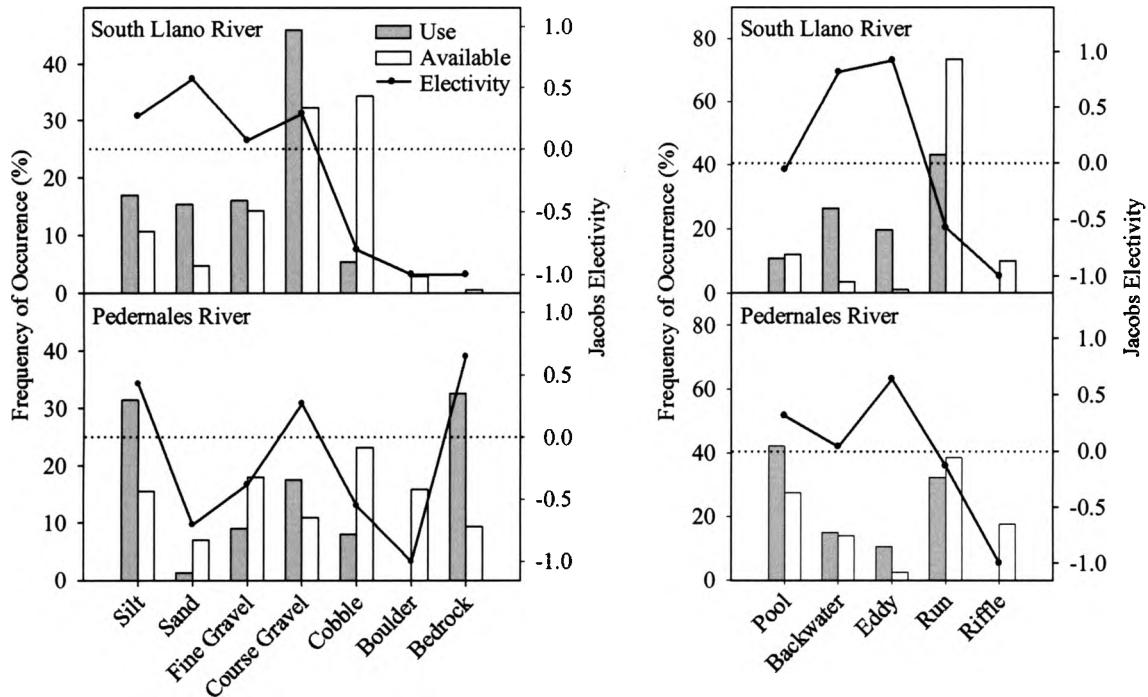

Figure 2.7: Mean percent use (grey bars), frequency occurrence of availability (white bars), and Jacobs (1974) electivity values (circles, solid line) for substrates and mesohabitats used by Guadalupe bass in the South Llano River and Pedernales River January through August 2008. Positive electivity values indicate preference and negative electivity values indicated avoidance.

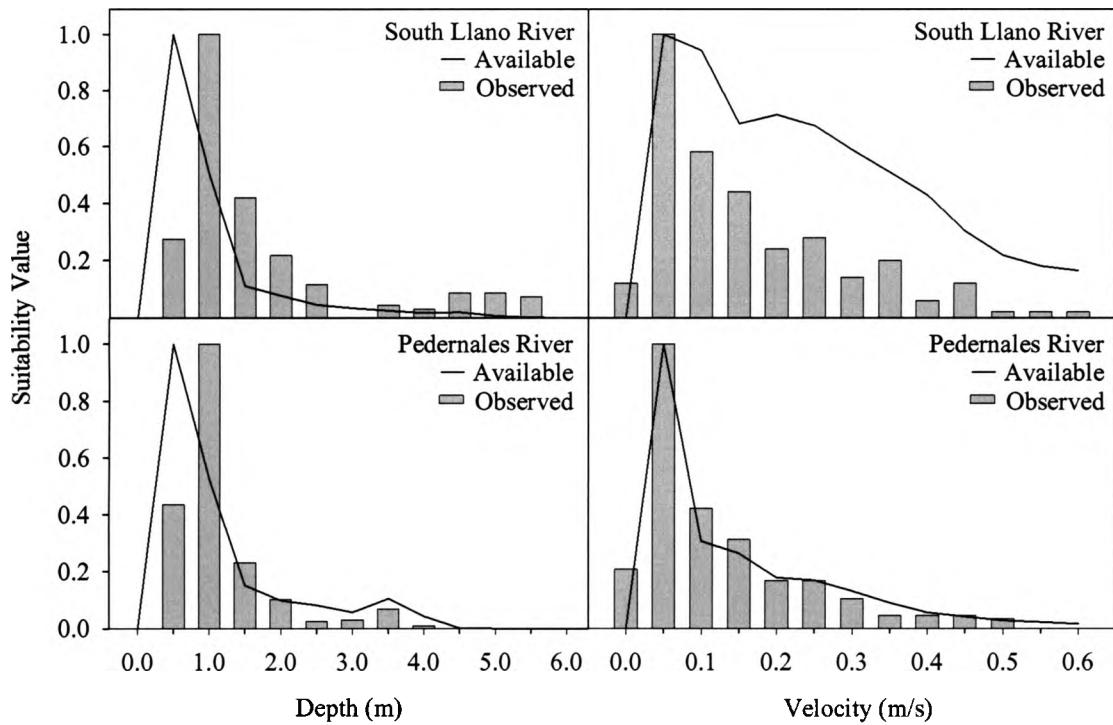

Figure 2.8: Suitability curves for observed habitat use (grey bars) and available habitat (solid line) in terms of depth (m) and velocity (m/s) for Guadalupe bass in the South Llano River ($n = 162$ observations) and Pedernales River ($n = 393$) between January and August 2008.

VITA

Joshuah S. Perkin was born September 7, 1982 in Abilene, Texas. After graduating from Cooper High School in 2001, he attended Cisco Junior College, Hardin Simmons University, and finally Texas State University-San Marcos, where he received his Bachelor of Science in Aquatic Biology in 2006. During this time, Josh worked as a fish ecologist for the Texas Parks & Wildlife Department, The Caddo Lake Institute, and Texas State University-San Marcos. Since January 2007, Josh has researched conservation of imperiled stream-dwelling fishes in the Aquatic Biology graduate degree program at Texas State University-San Marcos. In April 2009 Josh accepted an ecology and evolutionary biology doctoral student position at Kansas State University.
